The overflow spillway of Presa Marte R. Gómez, (on the Río San Juan), where the first specimen was found, flows directly into the Río Grande 14.5 km to the north, although most water is diverted into the Guillermo Rode irrigation canal before reaching the river. The second specimen was found 13.5 km S of the Río Grande, crossing a dirt road in arid thorn scrub where the nearest permanent surface water was the Guillermo Rode canal, located 3 km to the east. Based on these observations, *T. venusta* may also occur in Starr County, Texas.

The species may have been introduced to the border area through recreational and fishing activities at Presa Marte R. Gómez. Alternatively, the turtles may be moving northward through the extensive network of irrigation canals constructed in northern Tamaulipas over the past few decades. Another possibility is that the species emigrated overland from the vicinity of China, Nuevo León, were the headwaters of the Río San Lorenzo, a tributary of the Río San Fernando (Río Conchos on some maps) are separated from Presa El Cuchillo and Río San Juan (a Río Grande tributary) by a distance of ca. 10 km. Overland movements are well documented in *Trachemys* (Cagle 1944; Gibbons 1970, 1990). Gibbons et al. (1990) recorded mark and recapture distances as far as 9 km attributed to overland travel by turtles. Therefore, it is unclear if both adult individuals reported here represent members of an established population, a question for future research.

Distribution maps published in Ernst (1990), Legler (1990), and Seidel (2002) illustrate a gap between the ranges of *T. venusta* and *T. scripta* in northern Tamaulipas. Legler (1990) also states that little suitable habitat exists in the 110 km distance between the Río San Fernando and Río Grande near Brownsville, Texas, implying a natural barrier partitioning the two species. Indeed, Goldman (1951) reported traveling by wagon from Matamoros to San Fernando, 22–25 February 1902, without crossing a stream and Sutton (1972) noted the absence of water in this agricultural area during a trip, 6–8 January 1949. It should be noted however, that both Goldman and Sutton passed through the area during the December to May dry season (Martin 1958). Iverson (1992) and Auth et al. (2000) subsequently recorded *Trachemys* localities in this region and Seidel et al. (1999) mapped and discussed in detail several *T. scripta* and *T. venusta* sites, therein identifying a hiatus of no more than 10 km between the ranges of the two species. Seidel et al. (1999) concluded that because many bodies of water in this arid region are temporary, the two species may not contact each other. Although no concerted effort has been made on our part to identify the exact distributional limits of *T. scripta* and *T. venusta*, our field observations are generally consistent with Seidel et al. (1999), who determined that *T. scripta* occurs up to 85 km S of the Río Grande and that *T. scripta* and *T. venusta* do not hybridize. We have reservations about accepting a hiatus between the two species in northern Tamaulipas. Our field surveys include multiple observations of *Trachemys* in this region, including *T. scripta* occurring 75 km and *T. venusta* occurring 90 km S of the Río Grande and that they do not normally inhabit the same locality (but see below). Although the environment between the Río San Fernando and the Río Grande is primarily arid, numerous smaller ríos, arroyos, and resacas, some with names (north to south: Río El Tigre, Río El Diablo, Río Las Blancas, and Arroyo El Abra), and others without names, as well as marshland, manmade cattle tanks, and numerous irrigation canals provide substantial habitat for *Trachemys* within that previously perceived distributional gap. It is also possible that excess irrigation water is now channeled into those natural waterways increasing their normal volume and seasonal duration of water that would historically have been in these drainage systems. Field surveys revealed *Trachemys* and *Apalone*

spinifera living in many bodies of water, including roadside ditches, transected by Mexican Hwy 101 between Matamoros and San Fernando, and finding turtles crossing roads throughout the arid coastal plain was not unusual. Several *T. scripta* were observed in a cattle tank near a remote unpaved road in the municipality of Reynosa, 33 km SW junction of Hwy 40 and Hwy 2 in Reynosa (25.833611°N, 98.461667°W, 122.4 m elev.) near the Nuevo León border. Additionally, *T. scripta* are also known to enter brackish water and occupy barrier islands in Georgia and South Carolina (Ernst et al. 1994; Gibbons and Coker 1978). Dozens of lagunas of various sizes and degrees of salinity on the Gulf Coast could provide additional routes of dispersal in northern Tamaulipas.

Seidel et al. (1999) suggested that differences in courtship behavior limit interbreeding between *T. scripta* and *T. gaigeae* in the Río Grande. Legler (1990) also discusses sexual dimorphism (foreclaw length, snout profile) and how mating differences separated *Trachemys* in Texas from Mexican species. So perhaps factors associated with reproductive isolation separate *T. scripta* and *T. venusta* in Tamaulipas? Based on the color patterns of the carapace, we have never observed *Trachemys* that appeared to be hybrids. Seidel et al. (1999) addressed hybrids referred to by Legler (1990) from "La Laca (lat. 25-6, long. 98-7)" [= La Loca, properly named Aguila Azteca, 25.115278°N, 98.147222°W, 50 m elev., a locality in the Arroyo El Abra / Estero La Resaca drainage] and concluded that they were *T. venusta*. We have also never observed the two species occupying the same body of water, with the exception of the overflow spillway at Presa Marte R. Gomez, where *T. scripta* were observed on later occasions than the individual *T. venusta* from that locality reported above, and it may well have been introduced. Pritchard (1979) recorded *T. s. elegans* as far south as Ciudad Victoria, Tamaulipas, but Seidel et al. (1999) regarded those as likely introductions. We concur with Seidel et al. (1999) on that point and add that we have observed other probable introduced *T. scripta* in southeastern Tamaulipas at Cenote La Poza Verde (22.993056°N, 98.15556°W, 180 m elev.), a recreational area near El Nacimiento, 8 km NW of Aldama.

Lacertilia

Hemidactylus frenatus (Common House Gecko). Municipio Aldama: Hotel Rancho Viejo in Aldama (22.921667°N, 98.073333°W), 130 m elev. 1 June 2002. William Farr and Jerry Caraviotis. Verified by Michael R. J. Forstner. UTADC 1937. Municipio Antiguo Morelos, Antiguo Morelos (22.553889°N, 99.078056°W), 208 m elev. 29 March 1997. David Lazcano. Verified by Fernando Mendoza-Quijano. UANL 4479-80. Municipio El Mante: 25 km SE of Ciudad Mante (22.5225°N, 98.861111°W), 113 m elev. 15 October 2007. William Farr. Verified by Michael R. J. Forstner. UTADC 1941-42. Municipio Gonzalez: on the walls of the Bonito Inn in Gonzalez (22.821389°N, 98.434167°W), 79.8 m elev. 28 October 2004. William Farr. Verified by Michael R. J. Forstner. UTADC 1938. Municipio Ocampo: on the walls of Hotel Vergel in Ocampo (22.845833°N, 99.330556°W), 350 m elev. 23 September 2006. William Farr, James R. Dixon, and Toby J. Hibbitts. Verified by Michael R. J. Forstner. UTADC 1940. Municipio Ocampo: Poza Madre, 4 km S of Chamal Viejo, 11 km SE of Ocampo (22.78944°N, 99.234722°W), 228.9 m elev. 22 July 2006. Eli Garcia Padilla and William Farr. Verified by Fernando Mendoza-Quijano. UANL 6468. First state records and northernmost localities for the Atlantic slopes of México, and range extensions of 140 km, 54 km, 62 km, 109 km, 97 km, and 89 km N, respectively, from the nearest record in Ciudad Valles, San Luis Potosí [21.991944°N, 99.010556°W, 90 m elev.] (Marcellini 1971). During the period since Smith and Taylor (1950) recorded this lizard from the vicinity of Acapulco, Guerrero, it has become widespread in México (Ballardo et al. 1996).

We were unfortunately at fault during our surveys by considering *H. frenatus* to be of secondary interest because of its nonnative status and failed to collect adequate voucher specimens or keep complete records of its occurrence in other areas of the state. However, our limited information does indicate that viable populations were established in the municipalities of Gómez Farías, Jiménez, Llera, Tampico, Soto La Marina, and Jaumave, and we are certain it occurs in additional municipalities from Jiménez south. With the exception of an observation in a hotel in Jaumave (23.410278°N, 99.386389°W, 751 m elev.), located in the Jaumave Valley within the Sierra Madre Oriental, all other records were from the coastal plain at elevations below 350 m. The hotel in Jaumave is also one of the very few places where we observed *H. frenatus* occurring in sympatry with *H. turcicus*. Eighty-eight museum records of *H. turcicus* from Tamaulipas (19 examined by us) indicate that they were widespread in the state by the 1970s. However, we have rarely observed *H. turcicus* south of San Fernando in the last 15 years, suggesting that *H. frenatus* has displaced *H. turcicus* in the southern half of the state.

Hemidactylus frenatus are frequently associated with human structures and habitation and the vast majority of our observations have been on hotel and restaurant walls. Because it is an invasive species with the potential of having a detrimental effect on the native fauna, a few exceptions are worth noting. At Laguna del Carpintero, a park in the city of Tampico (22.238889°N, 97.8575°W, 1 m elev.) we observed two individuals while pealing bark from a dead tree in a densely wooded area ca. 500 m from any manmade structures. The El Mante specimen reported above, a juvenile, was found with a juvenile *Sceloporus variabilis*, under a cinder block in a dry concrete water trough and additional individuals were heard vocalizing in a water well about 2 m from the trough. The well and trough were located in thorn scrub that had been partially cleared for cattle grazing and completely devoid of any buildings. At the Poza Madre locality recorded above, situated at the end of a dead end road in what was otherwise undisturbed tropical deciduous and gallery forest, we found at least four deserted palapas supporting thatched roofs. The immediate area, perhaps 0.1 ha in size, had been cleared and intended for recreation, but appeared to be in a general state of abandonment. Numerous *H. frenatus* could be seen and heard vocalizing from the thatch roofs, and additional individuals, including the voucher specimen recorded here, were found inside dead logs in the immediate area. Deeper in the forest *H. frenatus* ceased to be observed, but various numbers of *Sceloporus variabilis*, *Lepidophyma sylvaticum*, *Ameiva undulata*, and *Ctenosaura acanthura* were detected there. Although *H. frenatus* is most commonly associated with human structures, it is able to utilize tropical deciduous forest and thorn scrub habitats, at least in disturbed areas.

Coleonyx brevis (Texas Banded Gecko). Municipio Reynosa: 37 km SW of junction of Hwy 40 and Hwy 2 in Reynosa (25.796389°N, 98.466667°W), 147 m elev. 13 August 2007. William Farr. Verified

by Fernando Mendoza-Quijano. UANL 6469. The southeastern-most locality within the species' geographic range (Dixon 1970), first municipality record, and a range extension of ca. 60 km S from the nearest locations in the vicinity of Mission/La Joya [26.2525°N, 98.494444°W, 38.5 m elev.], Hidalgo County, Texas (Axtell 1986). Although this species can be assumed to occur throughout the northwestern "panhandle" region of Tamaulipas due to the numerous records in adjacent areas of Texas and Nuevo León (Axtell 1986; Dixon 1970, 2000), this is only the second confirmed record from Tamaulipas. It was found under a tire in thorn scrub.

Crotaphytus collaris (Eastern Collared Lizard). Municipio Miquihuana: on the road to La Joya de Herrera, 8.5 km SW of Miquihuana (23.5375°N, 99.825556°W), 1651.8 m elev. 19 September 2007. William Farr and Tim Burkhardt. Verified by Michael R. J. Forstner. UTADC 1935. Municipio Bustamante: highway from El Capulin to Bustamante, km marker 14 (23.331944°N, 99.713333°W), 1350 m elev. David Lazcano. 8 September 1996. Verified by Fernando Mendoza-Quijano. UANL 4231. First municipality records that fill gaps between localities in the municipalities of Tula (Axtell and Webb 1995) and Jaumave (Farr et al. 2007), and confirms the occurrence of *C. collaris* in four of the five municipalities in Tamaulipas lying west of the Sierra Madre Oriental. Its occurrence should also be anticipated with near certainty at lower elevations in the arid canyons in the municipality of Palmillas, as these would be obvious dispersal routes east into the Jaumave Valley. The vegetation at both localities is Chihuahuan Desert scrub. Also of note, the color and pattern of *C. collaris* from Tamaulipas (22 observed in field surveys) are distinctly different from the more familiar Texas populations and agree with the description of *C. c. melanomaculatus* in Axtell and Webb (1995), although McGuire (1996) subsequently synonymized all subspecies of *C. collaris*.

Crotaphytus reticulatus (Reticulate Collared Lizard). Municipio Reynosa: 22 km SW of the junction of Hwy 40 and Hwy 2 in Reynosa. (25.933056°N, 98.428056°W), 103.5 m elev. 9 September 2007. Tim Burkhardt and William Farr. Verified by Michael R. J. Forstner. UTADC 1936. A range extension of 16 km E of the nearest record in McGuire (1996) and Montanucci (1976), expanding the distribution southeastward outside the panhandle region into northern Tamaulipas. The lizard was found perched on a large rock by a gravel road in thorn scrub.

Phrynosoma orbiculare (Mountain Horned Lizard). Municipio Bustamante: on the road to Las Antonias, 9.5 km W of Bustamante (23.405°N, 99.839772°W), 2004 m elev. 12 October 2007. William Farr. Verified by Fernando Mendoza-Quijano. UANL 6470. First municipality record and a range extension of 22 km SW of the only other confirmed record from the state (Horowitz 1955) at Miquihuana [23.575°N, 99.75°W, 1860 m elev.], 80 mi. [128.7 km] SW of Ciudad Victoria. The specimen was found DOR in high elevation Chihuahuan Desert scrub.

Aspidoscelis inornata (Little Striped Whiptail). Municipio Tula: 27 km SW of Cd. Tula (22.832222°N, 99.913056°W), 1067.1 m elev. 26 September 2006. Toby Hibbitts, James R. Dixon, and William Farr. Verified by Fernando Mendoza-Quijano. UANL 6471. First confirmed record for the state and a range extension of 30 km NE from the closest known locality in San Luis Potosí (Chaney and Liner 1995). Although maps in Wright (1994) and Axtell (1994) depict the distribution of the species in Tamaulipas, neither provided specific localities or data verifying that conclusion. Most publications, both prior and subsequent to 1994, do not record the species in the state (e.g., Axtell 1961; Conant and Collins 1998; Degenhardt et al. 1996; Lemos Espinal and Smith 2007a, 2007b; Smith and Smith 1976; Smith and Taylor 1966; Stebbins 2003; Walker et al. 1996; Wright 1968; Wright and Lowe 1993). We have only observed *C. inornata* in the municipality of Tula, in extreme southwestern Tamaulipas, in Chihuahuan Desert scrub; however, it is locally very abundant in that area.

Gerrhonotus infernalis (Texas Alligator Lizard). Municipio Soto La Marina: 14 km SW of Soto La Marina on the "old" highway 70, in the northeastern foothills of the Sierra de Tamaulipas (23.655278°N, 98.339444°W), 228.9 m elev. 9 October 2005. William L. Farr. Verified by Fernando Mendoza Quijano. UANL 6437. A range extension of 110 km E from the closest locality in the vicinity of Gómez Farías, 1 km WNW of Pano Ayuctle, ca. 150 m elev. [23.123611°N, 99.165278°W] (Martin 1958). The easternmost locality in Tamaulipas and the first record from the isolated Sierra de Tamaulipas (Good 1988, 1994). This specimen was found DOR in localized tropical deciduous forest that occurs at lower elevations of the Sierra de Tamaulipas between the thorn scrub of the coastal plain and pine-oak forest of higher elevations.

Serpentes

Coniophanes fissidens (Yellow-bellied Snake). Municipio Tula/Ocampo (near border): on the trail from Emperadores Aztecas to Lagunas Las Hondas, 31 km SE of Tula. (22.790833°N, 99.54°W), 1228.2 m elev. 19 July 2006. Eli García Padilla and William Farr. Verified by Jonathan Campbell. UTADC 1930–34. Northernmost record for the species in México, first state record, and a range extension of 28 km NW from the closest known locality at El Salto, San Luis Potosí [22.586111°N, 99.383333°W, 450 m elev.] (Taylor 1953). This snake was found inside a large decaying log in humid oak forest. In the course of researching this account, it became apparent that, as Myers (1969) indicated 40 years ago, *C. fissidens* is in need of an updated review, as Bailey (1939) and Fisher (1968; unpubl. thesis) were the last complete evaluations of this species (Lee 1996; Savage 2002; Wilson and Meyer 1985). The most widespread species in the genus, *C. fissidens*, reportedly ranges from Ecuador (Cadle 1989) northward into México. However, there has been confusion regarding the actual distributional range on the Atlantic versant of México, with various authors (e.g., Campbell 1998; Köhler 2008; Köhler et al. 2006; Lee 2000; Peters and Orejas-Miranda 1970) describing the northern limit as southern Veracruz, central Veracruz, or San Luis Potosí.

Lampropeltis mexicana (San Luis Potosí Kingsnake). Municipio Jaumave: On the road to Avila y Urbina, 31 km NW of Jaumave (23.601944°N, 99.6025°W), 1703 m elev. 15 October 2006. William Farr and Andrew Godambe. Verified by Fernando Mendoza-Quijano. UANL 6472. The second state and first municipality record and a range extension of 16 km E from the only published locality for species in Tamaulipas at Miquihuana [23.574722°N, 99.752222°W, 1833 m elev.], the type locality of *L. thayeri* (Garstka 1982; Gehlbach 1967; Loveridge 1924). The snake was found under a rock in dry pine-oak forest. Bryson et al. (2007)

recently presented evidence that *L. mexicana* is polyphyletic, with the implication that populations in the Sierra Madre Oriental of Tamaulipas are not conspecific with *L. mexicana*.

Pantherophis bairdi (Baird's Rat Snake). Municipio Hidalgo: road to Conrado Castillo (24.018333°N, 99.484167°W) [1200 m elev., 44 km NW of Ciudad Victoria]. 18 October 2001. Pablo A. Lavín Murcio. Verified by Fernando Mendoza-Quijano. UTADC 1956. Municipio Victoria: 10 mi. [16.09 km] SW of Ciudad Victoria on Rt. 101 [ca. 23.6°N, 99.2°W, 1200 m elev.]. 22 September 1969. T. W. Walker. Verified by Juan E. de Jesus. AMNH R 104464. New municipality records for each, first confirmed records from the Sierra Madre Oriental of Tamaulipas, and range extensions of 87 km SW, and 115 km SW, respectively, from the only confirmed records from Tamaulipas in the Sierra San Carlos (Schulz 1996). Although Lemos Espinal and Smith (2007a) included the Sierra Madre Oriental of Tamaulipas to be within the species range, no locality data were provided. In addition to the records above, Alan Kardon (pers. comm.) showed us photographs of *P. bairdi* he observed in the vicinity of Las Joyas de Miquihuana [ca. 11 km N of La Peña, 23.65°N, 99.7°W, 2900 m elev.] in the municipality of Miquihuana, confirming its occurrence there. The vegetation at the Hidalgo and Miquihuana municipality localities is dry pine-oak and juniper forest, and oak forest at the site in the municipality of Victoria. The localities recorded here, combined with three records from the Sierra San Carlos (specimens examined by Lawson and Lieb 1990, and mapped in Schulz 1996) collectively represent every record of *P. bairdi* from Tamaulipas known to us. We suspect that these localities represent the southern limit of the species distribution, but the occurrence of this uncommon and secretive snake cannot be ruled out from high elevation areas supporting pine, oak, and juniper habitats farther south in the municipalities of Bustamante, Palmillas, and Tula.

Rhadinaea gaigeae (Gaige's Pine Forest Snake). Municipio Casas: 8 km N of Rancho La Sauceda in the Sierra de Tamaulipas [50 km N of Manuel] (23.197222°N, 99.340833°W), [1140 m elev.]. 21 January 2005. Gilberto Herrera. Verified by Fernando Mendoza-Quijano. UTADC 1957. First record from the isolated Sierra de Tamaulipas, easternmost record in the state (Myers 1974), and range extension of 88 km E from the nearest localities in the Sierra de Guatemala (Martin 1958). The vegetation in the area is predominately pine-oak forest.

Tantilla atriceps (Mexican Black-headed Snake). Municipio Tula: Las Cruces (= Colonia Agrícola), 25 km S of Tula (22.765556°N, 99.679722°W), 1021.8 m elev. 17 July 2006. William Farr and Eli García Padilla. Verified by Fernando Mendoza-Quijano. UANL 6473. The first confirmed record from southwestern Tamaulipas (an isolated population is recorded from the Sierra de San Carlos in the north-central region of the state) and a range extension of ca. 60 km W from the closest known locality in San Luis Potosí (Cole and Hardy 1981, 1983). The snake was found under a stone near abandoned buildings surrounded by Chihuahuan Desert scrub vegetation.

Tantilla wilcoxi (Chihuahuan Black-headed Snake). Municipio Bustamante: Near La Joya de Herrera, 7 km W of the town of Bustamante (23.420278°N, 99.820278°W), 1916.4 m elev. 19 September 2007. Tim Burkhardt and William Farr. Verified by Fernando Mendoza-Quijano. UANL 6474. First record for Tamaulipas and a range extension of ca. 125 km SE of the nearest locality in Nuevo León (Liner 1983). The snake was found under a rock in a pasture surrounded by Chihuahuan Desert scrub that contained scattered juniper trees.

Trimorphodon tau (Mexican Lyresnake). Municipio Palmillas: on the road to Miquihuana, 10.5 km N of Cd. Palmillas (23,3925°N, 99.605833°W), 1520.7 m elev. 12 October 2007. William Farr. Verified by Fernando Mendoza-Quijano. UANL 6476. First municipality record and range extension of 40 km NW from the nearest locality at La Joya de Salas [23.172222°N, 99.3°W] in the Sierra de Guatemala (Martin 1958). It is also the first published record from the plateau and interior canyons and valleys of the Sierra Madre Oriental of Tamaulipas, although museum records (not examined by authors) collected subsequent to McDiarmid and Scott (1970) are from interior localities. Other publications following McDiarmid and Scott (1970) have reported northward range extensions for the species in Tamaulipas and Nuevo León (e.g., Blody et al. 1987; Contreras-Lozano et al. 2007; Dundee and Liner 1997; Lazcano et al. 1992; Nevárez 1999). This snake was found DOR in Chihuahuan Desert scrub containing some scattered juniper trees.

Tropidodipsas fasciata (Banded Snail Sucker). Municipio Hidalgo: 12 km W of Villa Hidalgo, on the road to El Chorrito (24.251944°N, 99.558056°W), 450 m elev. 27 September 2006. Toby Hibbitts, William Farr, and James R. Dixon. Verified by Fernando Mendoza-Quijano. UANL 6475. Northernmost record for the species and a range extension of 72 km NW from the closest recorded locality reported by Jackson (1971) from 25.7 km NNE of Ciudad Victoria near Parque Nacional Río Corona, Hwy 101 and Río Corona (22°56'N, 98°56'W [coordinates in error, this locality is 23°56'N, 98°56'W = 23.933333°N, 98.933333°W, 140 m elev.]). The Jackson (1971) locality was later mapped in Kofron (1987). The habitat west of Villa Hidalgo, where this specimen was found DOR, is located near the base of the Sierra Madre Oriental where the mountains abruptly rise from the arid coastal plain. The canyons and surrounding landscape at the base of the eastern Sierra Madre Oriental, ranging as far north as the Iturbide/Linares Canyon in Nuevo León, support a narrow and sometimes disjunct band of relatively lush vegetation with elements of tropical deciduous and gallery forest. In addition, Parque Nacional Río Corona has been a popular destination for U.S. biologists and bird watchers, but has never been officially designated a national park by the Mexican Government.

Micrurus tener (Texas Coral Snake). Municipio Jaumave: on the road to Avila y Urbina, 13.5 km NW of Jaumave (23.435556°N, 99.510278°W), 1120.5 m elev. 17 September 2007. Tim Burkhardt and William Farr. Verified by Fernando Mendoza-Quijano. UANL 6477. Municipio Tula: 16 km SW of Tula near Ejido San Pablo (22.900556°N, 99.827778°W), 1066 m elev. 12 October 2005. William Farr and Tiffany Kosch. Verified by Michael R. J. Forstner. UTADC 1944. The first records of this species occurring in and west of the Sierra Madre Oriental in Tamaulipas, and range extensions of ca. 51.5 km SW for the Jaumave municipality record, and ca. 60 km W for the Tula municipality record (Campbell and Lamar 2004; Roze 1996). These records partially fill a gap in this species' distribution on the Mexican Plateau between populations to the north in eastern Coahuila and to the south in Guanajuato,

Querétaro, and Morelos (Campbell and Lamar 2004). Hernández-Ibarra (2005) and Hernández-Ibarra and Ramírez-Bautista (2006) also recorded *M. tener* from the municipality of Guadalcázar, San Luis Potosí adjacent to municipality of Tula, Tamaulipas, but did not provide locality details. The Jaumave municipality record was collected DOR in a canyon rising from the western slope of the Jaumave Valley where the vegetation transitions from thorn scrub to dry pine-oak and juniper forest. The Tula municipality record was found crawling at night in Chihuahuan Desert scrub.

Acknowledgments.—Fieldwork was conducted under SEMARNAT permits 7150/97, 01624/05, 00800/06, 01085/07, 01255/08, FAUT-0045. Houston Zoo, Inc. provided funds and time for fieldwork and research. We thank James R. Dixon, Toby Hibbitts, and Heather Prestridge for allowing us access to the TCWC collection and Dixon's library, accommodating loans from various institutions on our behalf, and for their ongoing advice and encouragement. We thank the following individuals for accommodating us on visits to examine material held in their respective institutions or providing loans: Jack Sites (BYU); Robert Henderson (MPM); Cybil Smith and Karen McBee (OSUS); Steven Platt (SRSU); Alejandra Salinas-Camarena (UANL); Christopher Phillips, Dan Wylie, Eric Johnston, and Michael Dreslik (UIMNH); and Traci Hartsell, Steve Gotte, Kenneth Tighe, Robert Wilson, and Ronald Heyer (USNM). Amy Lathrop, Ross MacCulloch, and Robert Murphy (ROM) provided photographs of specimens for us to examine. John Simmons (KU), Amy Estep (OKMNH), and Chris Conroy (MVZ) kindly provided data for referenced specimens that were not examined by us. We also express gratitude to everyone recognized in the text for verifying specimens. For advice on miscellaneous matters, we thank Ralph W. Axtell, Carl H. Ernst, Michael R. J. Forstner, Joseph P. Flanagan, Alan Kardon, and Michael E. Seidel. For accompanying us in the field and sharing their knowledge, time, and assistance, we express thanks to George Brandy, Tim Burkhardt, Jerry Caraviotis, José Cortes-Lariva, James R. Dixon, Ricardo Enrique-Nuñez, Oscar M. Hinojosa-Falcón, Adam Ferguson, Michael R. J. Forstner, Oscar Gallardo, Andrew Godambe, Gilberto Herrera-Patiño, Toby Hibbitts, Tiffany Kosch, Armando Martínez, Omar Martínez-Alvirde, Eli García-Padilla and David Rodríguez.

**Corresponding author; email: urigarcia@gmail.com*

Until recently, the diversity and distribution patterns of the herpetofauna within the state of Puebla, México, were not well known (Canseco-Márquez et al. 2000). However, with the discovery of new distributional records (e.g., Canseco-Márquez et al. 2003, 2004, 2005; Canseco-Márquez and Gutiérrez-Mayén 2006; García-Vázquez et al. 2006; Solano-Zavaleta et al. 2006) and descriptions of new species (Canseco-Márquez et al. 2002; Canseco-Márquez and Smith 2004; Parra-Olea et al. 2004), the number of amphibians and reptiles known to occur within the state has increased significantly. There continue to be mostly unexplored regions in Puebla, one of which was, until recently, the Sierra Negra located in the southeastern portion of the state.

During 2006 and 2007 we conducted field trips to the Sierra Negra and verified 18 new records for Puebla (9 amphibians and 9 reptiles) and confirmed 16 other noteworthy distributional accounts (5 amphibians and 11 reptiles). Collections were made by the authors, all verified by Alberto Mendoza Hernández, and all vouchers were deposited in the collection of Museo de Zoología, Facultad de Ciencias, UNAM (MZFC). All locality coordinates were taken with a Garmin GPS unit, using map datum WGS84. Distances between localities are airline measures. Common and scientific names, unless more recently revised, follow those found in Liner and Casas-Andreu (2008). Species listed are arranged in alphabetical order by their family names. Vegetation classification follows Rzedowski (1978).

New State Records

Anura

Incilius valliceps (Southern Gulf Coast Toad). Municipality of Eloxochitlán: 2 km SW of La Pedrera (18.4856ºN, 96.857ºW), 123 m elev. 26 July 2006. MZFC 20499-50. Along Rancho Nuevo-Tepeyac Road (18.487ºN, 96.866ºW), 125 m elev. 27 July 2006. MZFC 20520. Municipality of Tlacotepec de Díaz: Tlacotepec de Díaz (18.4058ºN, 96.845ºW), 255 m elev. 29 June 2007. MZFC 21958–59. These records fill gaps between localities in adjacent Oaxaca and Veracruz (Mendelson 1998). All vouchers, except MZFC 20520, were found in water pools either in solitary or as amplexing pairs. All localities contained tropical semideciduous forest.

Hyalinobatrachium fleischmanni (Fleischmann's Glass Frog). Municipality of Eloxochitlán: Tepequezquiapan (18.4862°N, 96.916°W), 1041 m elev. 27 June 2007. MZFC 20529, 21948–50. These records extend the known range about 78 km NW from localities in northern Oaxaca (Lips et al. 2004). All frogs were found calling while sitting on leaves in cloud forest.

Eleutherodactylus leprus (Leprus Chirping Frog). Municipality of Zoquitlán: along El Tepeyac-Tlacotepec de Díaz Road (18.4443°N, 96.857°W), 91 m elev. 26 July 2006. MZFC 20507. A range extension of ca. 74 km SE of Coyame, Veracruz, filling a gap between localities in central Veracruz and northern Oaxaca (Lynch 1970). The frog was found calling from a tree branch in tropical evergreen forest.

Agalychnis callidryas (Red-eyed Leaf Frog). Municipality of Tlacotepec de Díaz: along El Tepeyac-Tlacotepec de Díaz Road (18.4247ºN, 96.851ºW), 115 m elev. 26 July 2006. MZFC 20501, 20508, 20516. This locality represents a range extension of about 131 km WNW of Los Mangos, Playa Escondida, in Central Veracruz (Duellman 2001). All frogs were males found calling from branches of bushes located near a pond surrounded by tropical semideciduous forest.

Dendropsophus microcephalus (Small-headed Treefrog). Municipality of Tlacotepec de Díaz: along Tepeyac-Tlacotepec de Díaz Road (18.418ºN, 96.854ºW), 107 m elev. 27 July 2006. MZFC 20503, 20509, 20510, 20519. This locality represents a range extension of about 178 km W of 2.4 km N Juan Díaz Covarrubias, the nearest locality known in central Veracruz (Duellman 2001). The frogs were found in tropical semideciduous forest.

Ptychohyla zophodes (Gloomy Mountain Stream Frog). Municipality of Eloxochitlán: 1 km S Eloxochitlán (18.5098°N, 96.95°W), 1332 m elev. 27 July 2006. MZFC 22150. A range extension of 50 km NE of the type locality, 16.1 km W of Jalapa de Díaz, on the Gulf versant of northern Oaxaca (Campbell and Duellman 2000). The frog was found calling from a tree branch in cloud forest.

Smilisca cyanosticta (Blue-spotted Mexican Treefrog). Municipality of Eloxochitlán: Tepequezquiapan (18.4862°N, 96.916°W), 1041 m elev. 27 June 2007. MZFC 20530. The record extends the range ca. 105 km W of Dos Amates, in central Veracruz (Duellman 2001). The frog was found calling from a pond in cloud forest.

Leptodactylus melanonotus (Sabinal Frog). Municipality of Tlacotepec de Díaz: along El Tepeyac-Tlacotepec de Díaz Road (18.423ºN, 96.851ºW), 133 m elev. 29 June 2006. MZFC 22151. First verified record from Puebla, extending the known range 86 km NW from the nearest locality at Tuxtepec, Oaxaca (Juárez-López et al. 2006). The species was reported from Puebla by Smith and Taylor (1966), but they mentioned no specific locality. The specimen was found in tropical semideciduous forest.

Lithobates vaillanti (Vaillant's Frog). Municipality of Tlacotepec de Díaz: Tlacotepec de Díaz (18.4058°N, 96.845°W), 255 m elev. 29 June 2007. MZFC 21961. This record represents a range extension of about 48.5 km SW from the nearest known locality at Córdoba, Veracruz (Hillis and de Sá 1988). The frog was found in a patch of tropical semideciduous forest.

Lacertilia

Anolis cymbops (Cope's Veracruz Anole). Municipality of Eloxochitlán: Tepequezquiapan (18.4862ºN, 96.916ºW), 1041 m elev. 27 July 2006. MZFC 22173. This record extends the known range ca. 45 km S from Cuautlapan, Veracruz (Nieto-Montes de Oca 1994). The specimen was captured in cloud forest.

Anolis tropidonotus (Greater Scaly Anole). Municipality of Eloxochitlán: El Crucero (18.4887ºN, 96.887ºW), 569 m elev. 26 July 2006. MZFC 22171. Tepequezquiapan (18.4749ºN, 96.918ºW), 978 m elev. 27 June 2007. MZFC 21952. El Tepeyac (18.4877ºN, 96.854ºW), 94 m elev. 29 June 2007. MZFC 20538, 21954–55. 30 June 2007. These records extend the known range ca. 44 km SE from Cuautlapan, Veracruz (Luna-Reyes 2006). All lizards were found in a tropical semideciduous forest.

Sphenomorphus cherriei stuarti (Stuart's Brown Forest Skink). Municipality of Eloxochitlán: Tepequezquiapan (18.4862ºN, 96.916ºW), 1041 m elev. 28 June 2007. MZFC 22178. Extends the known range ca. 45 km SE from Potrero Viejo, Cuautlapan, Veracruz (Smith and Taylor 1966). The lizard was captured in a tropical semideciduous forest.

Xenosaurus grandis (Knob-scaled Lizard): Municipality of Eloxochitlán: Tepequezquiapan (18.4749ºN, 96.918ºW), 978 m elev. 27 June 2007. MZFC 22176. Extends the known range of the species ca. 47 km SE from Orizaba, Veracruz (King and Thompson 1968). The specimen was found in a tropical semideciduous forest.

Serpentes

Lampropeltis triangulum polyzona (Atlantic Central American Milksnake). Municipality of Eloxochitlán: Tepequezquiapan (18.4862ºN, 96.916ºW), 1041 m elev. 28 June 2007. MZFC 22157. Extends the range ca. 104 km S from Xico, Veracruz (Perez-Higareda and Smith 1991). The specimen was collected in tropical semideciduous forest.

Leptodeira polysticta (Small-spotted Cat-eyed Snake). Municipality of Eloxochitlán: Tepequezquiapan (18.4862ºN, 96.916ºW), 1041 m elev. 28 June 2007. MZFC 20533. This record extends the known range ca 40 km S from Amatlan de los Reyes, Veracruz (Perez-Higareda and Smith 1991). The snake was captured in a tropical semideciduous forest.

Oxyrhopus petola (Calico False Coral Snake). Municipality of Eloxochitlán: Tepequezquiapan (18.4862ºN, 96.916ºW), 1041 m elev. 28 June 2007. MZFC 21953. This record extends the known range ca. 168 km NW from Hueyapan, Veracruz (Perez-Higareda and Smith 1991). The specimen was captured in a tropical semideciduous forest.

Micrurus diastema (Variable Coralsnake). Municipality of Eloxochitlán: Tepequezquiapan (18.4862ºN, 96.916ºW), 1041 m elev. No specific date. MZFC 19735. A range extension of about 39 km N of Cuauhtémoc, Córdoba, Veracruz (Júarez-López et al. 2006). The snake was found in tropical semideciduous forest.

Typhlops tenuis (Coffee Blindsnake). Municipality of Eloxochitlán: El Tepeyac (18.4877ºN, 96.854ºW), 94 m elev. 30 June 2007. MZFC 22152. Extends the range 47 km S from Cordoba, Veracruz (Perez-Higareda and Smith 1991). The specimen was collected in tropical semideciduous forest.

Range Extensions

Anura

Craugastor loki (Rana del Volcan San Martin): Municipality of Eloxochitlán: Tepequezquiapan (18.4749ºN, 96.918ºW), 978 m elev. 27 June 2007. MZFC 20531–32. Municipality of Tlacotepec de Díaz: El Tepeyac (18.423ºN, 96.851ºW), 133 m elev. 29 June 2007. MZFC 21960. 1 km S of Tlacotepec de Díaz (18.4058ºN, 96.845ºW), 255 m elev. 29 June 2007. MZFC 21962. Together, these comprise the second, third, and fourth records for Puebla and represent a ca. 53 km NW range extension from the closest known locality at San Jose Tenango, Oaxaca (Lynch 2000). The closest known Puebla record is from Cuetzalan del Progreso, about 180 km NW of our localities (Canseco-Márquez and Gutiérrez-Mayén 2006; as *C. rhodopis*). The frogs were found in leaf litter in tropical semideciduous forest.

Craugastor pygmaeus (Pigmy Robber Frog). Municipality of Coyomeapan: road to Coyomeapan near Tilancingo stream (18.393ºN, 97.068ºW), 2530 m elev. 8 July 2008. MZFC 22280. Southernmost record for Puebla, and about a 172 km NNW range extension in the state from Ocotlán de Betancourt, Municipality of Tlatlauquitepec, Sierra Norte de Puebla, and bridges the distri-

butional gaps between reported localities in Oaxaca and Veracruz (Solano-Zavaleta 2008).

Ecnomiohyla miotympanum (Small-eared Treefrog). Municipality of Eloxochitlán: along Eloxochitlán-Tlacotepec de Díaz Road (18.4862°N, 96.916°W), 1041 m elev. 27 July 2006. MZFC 22148–49, 22154–56. Bridges a distributional gap between Xocayucan, Municipality of Tlatlauquitepec, Sierra Norte de Puebla, 168 km NNW (Solano-Zavaleta 2008) and along Puente de Fierro Road at Río Eloxochitlán in northern Oaxaca, 38 km S (Duellman 2001). The specimens were collected in cloud forest.

Scinax staufferi (Stauffer's Long-nosed Treefrog). Municipality of Tlacotepec de Díaz: along Tepeyac-Tlacotepec de Díaz Road (18.418ºN, 96.854ºW), 107 m elev. 27 July 2006. MZFC 20502, 20517–18. Southernmost record for Puebla, extending the range ca. 42 km from a site located 40 km W of Orizaba, Veracruz (Duellman 2001). The frog was found in tropical semideciduous forest.

Leptodactylus fragilis (White-lipped Frog). Municipality of Tlacotepec de Díaz: along El Tepeyac-Tlacotepec de Díaz Road (18.4247ºN, 96.851ºW), 115 m elev. 26 July 2006. MZFC 22153. Municipality of Eloxochitlán: Ejido el Tepeyac (18.4877ºN, 96.854ºW), 94 m elev. 29 June 2007. MZFC 22158. Southernmost record for Puebla and a range extension of ca. 184 km NNW of the other reported locality in the state, Municipality of Cuetzalan del Progreso, Sierra Norte de Puebla (Canseco-Márquez and Gutiérrez-Mayén 2006) and ca. 40 km SW from the closest localities in central Veracruz (Heyer et al. 2006). The frogs were found in tropical semideciduous forest.

Lacertilia

Corytophanes hernandezii (Hernandez's Helmeted Basilisk). Municipality of Eloxochitlán: El Tepeyac (18.4877ºN, 96.854ºW), 94 m elev. 30 June 2007. MZFC 20543. Southernmost record for the state and ca.193 km NNW range extension from the only other Puebla locality at Quetzapa, Tlatlauquitepec (Solano-Zavaleta 2008). The specimen was captured in a tropical semideciduous forest.

Hemidactylus frenatus (Common House Gecko). Municipality of Tlacotepec de Díaz: La Pedrera (18.4877ºN, 96.854ºW), 87 m elev. 26 July 2006. MZFC 20498. Municipality of Eloxochitlán: El Tepeyac (18.493ºN, 96.837ºW), 94 m elev. 30 June 2007. MZFC 20540, 21985. Southernmost records for the state that fill a gap between Mixteca de Puebla, Puebla (ca. 171 km WNW) (García-Vázquez et al. 2006) and Agustín Millán, Orizaba, Veracruz (ca. 47 km N) (Vázquez-Cisneros 2006). The lizards were collected on the walls of a house located in a tropical semideciduous forest.

Sceloporus variabilis (Rose-bellied Lizard). Municipality of Eloxochitlán: along Rancho Nuevo-El Tepeyac Road (18.487°N, 96.866°W), 125 m elev. 1 July 2007. MZFC 20542. El Tepeyac (18.4877ºN, 96.854°W), 94 m elev. 29 June 2007. MZFC 22159. Southernmost records for the state, extending the known distribution in Puebla 169 km SSE of Xocayucan, Tlatlauquitepec (Solano-Zavaleta 2008). The nearest known locality is Coscomatepec, Veracruz, located about 66 km NNE of our localities (Mendoza-Quijano et al. 1998).

Anolis laeviventris (White Anole). Municipality of Eloxochitlán: 1 km W of Eloxochitlan (18.5098ºN, 96.95ºW), 1041 m elev. 27 July 2006. MZFC 22175. Southernmost record for the state, extending the known range in Puebla 172 km SE of Caltepec, Tlatlauquitepec (Solano-Zavaleta 2008), and 44 km S of the nearest known locality at Orizaba, Veracruz (Mendoza-Quijano and Nieto-Montes de Oca 1995). The specimen was captured in tropical semideciduous forest.

Anolis sericeus (Silky Anole). Municipality of Tlacotepec de Díaz: Tlacotepec de Díaz (18.4058°N, 96.845°W), 255 m elev. 29 June 2007. MZFC 21957. Southernmost record for the state extending the range ca. 55 km S of the closest known locality at Cordoba, Veracruz, and also fills a gap between more northern localities in Puebla and Veracruz, and in Oaxaca (Lee 1980). The specimen was captured in a tropical semideciduous forest.

Scincella silvicola (Taylor's Ground Skink): Municipality of Eloxochitlán: 2 km E of El Tepeyac (18.487ºN, 96.866ºW), 125 m elev. 27 July 2006. MZFC 22172. Southernmost record for Puebla, extending the known range in the state 160 km SE of Tzinacapan, Cuetzalan del Progreso (García-Vázquez 2003), and ca. 44 km S of the nearest locality at San Lorenzo, Córdoba, Veracruz (Taylor 1937). The specimen was captured in a tropical semideciduous forest.

Ameiva undulata (Rainbow Ameiva): Municipality of Eloxochitlán: 2 km E of El Tepeyac (18.487ºN, 96.866ºW), 125 m elev. 1 July 2007. MZFC 20541. Previously known only from the northern part of the State (Echternacht 1971), and a range extension of ca. 43 km S from the closest known locality at Cuautlapan, Veracruz. The specimen was captured at roadside in a remnant patch of tropical semideciduous forest.

Serpentes

Geophis semidoliatus (Broken-ringed Earth Snake). Municipality of Eloxochitlán: Tepequezquiapan (18.4862°N, 96.916ºW), 1041 m elev. 28 June 2007. MZFC 22177. Southernmost record for the state. Previously only known from Puebla ca. 171 km NNW in the Sierra Norte region (Canseco-Marquez et al. 2000). Its closest known locality is ca. 24 km S at Cuautlapan, Veracruz (Pérez-Higareda and Smith 1991).

Imantodes cenchoa (Cope's Blunt-headed Tree Snake). Municipality of Eloxochitlán: Tepequezquiapan (18.4862°N, 96.916ºW), 1041 m elev. 28 June 2007. MZFC 20534. Southernmost record for the state. Previously only known from Puebla 171 km NNW in the Sierra Norte region (Solano-Zavaleta 2008). Its closest known locality is from 26 km NE at Otatitlán, Veracruz (Pérez-Higareda and Smith 1991).

Leptophis mexicanus (Mexican Parrot Snake). Municipality of Eloxochitlán: along El Crucero-Tlacotepec de Díaz Road (18.4768°N, 96.875ºW), 292 m elev. 26 July 2006. MZFC 20514. Extends the range ca. 24 km SW of the nearest localities at Motzorongo, Veracruz (Pérez-Higareda and Smith 1991), and fills a distributional gap between more northern localities in Puebla and Veracruz. The specimen was captured AOR surrounded by tropical semideciduous forest.

Ninia sebae (Common Red-backed Coffee Snake). Municipality of Eloxochitlán: Tepequezquiapan (18.4862ºN, 96.916ºW), 1041 m elev. 28 June 2007. MZFC 20535, 20560. Southernmost records

for the state, extending the range from Cuetzalan del Progreso, located ca. 180 km NW (Canseco-Márquez and Gutiérrez-Mayén 2006) and 26 km NNE of the closest known locality at Minatitlán, Veracruz (Pérez-Higareda and Smith 1991).

Acknowledgments.—Support for field work was provided by grants to Adrián Nieto-Montes de Oca from CONACyT (number P47590-Q) and the Dirección General de Apoyo al Personal Académico, Universidad Nacional Autónoma de México (PAPIIT number 210707). We thank R. Lares-Valdez, and J. García-Bocardo for their invaluable help in collecting specimens during 2007.

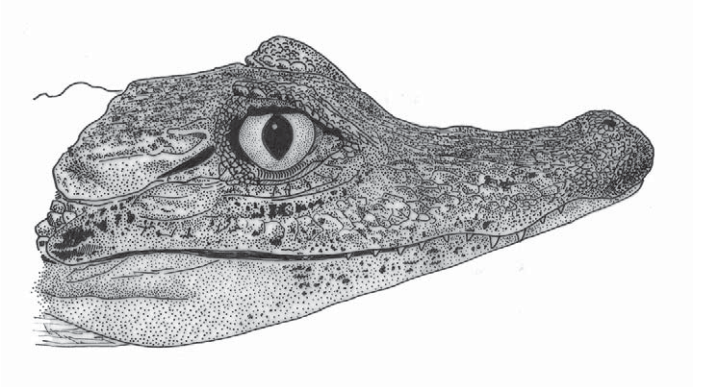
> *"When I was a boy of fourteen, my father was so ignorant I could hardly stand to have the old man around. But when I got to be twenty-one, I was astonished by how much he'd learned in seven years."*
>
> *—Mark Twain*

A recurring theme at professional zoo conferences is young people announcing discoveries or revelations that are new to them, as though they are "new" to everyone. This natural hubris often ends with an embarrassing sting when the young person realizes that his older colleagues know far more than he anticipated. After reading *The Lives of Captive Reptiles*, I realize I've been guilty of hubris on a grander, historical scale. Much of the foundational knowledge in our field was assembled far earlier than I realized, and some of what I thought I knew was shattered by careful science done 50, 80, or even 100 years ago. This book is not a "page-turner" in the vernacular sense, and certainly would not appeal to the broad audience of amateur herpetoculturists. But for career zoo herpetologists and serious terrarium practitioners, it offers a one-stop retrospective of the contributions made by terrarium science. If you want to know whose shoulders you're standing on, this book is worth reading.

The work is, in large part, a historical review, and the author combed an enormous body of international literature—formal and informal, well known and obscure—to produce an encyclopedic survey. Petzold completed this volume in 1982, and died prior to its printing in book form, so the state of terrarium science he describes is more than 25 years old. But the breadth of the backward look easily makes up for the lack of near-term information. The book is a sweeping amalgamation of more than 150 years of terrarium science and observation. The literature cited section alone is a wonderful resource.

But the book is more than just a historical summary. Petzold is making an extended argument for the scientific and conservation value of terrarium herpetology. The author expends as much effort defining the gaps in our collective knowledge as celebrating the achievements. Time and again he points out open fields of research for future terrarium practitioners, suggesting specific approaches to resolving questions. In many cases his suggestions were prescient, and subsequent research has since shed light on questions he posed. Throughout the text Petzold argues that observational and experimental research is central to the responsibilities of terrarium practice, particularly in zoos. He argues for careful observation and record keeping, acquiring specimens of known locality, and collaborating with natural history museums to maximize the research impact of living collections. Unfortunately 25 years after the book's original publication, none of these suggestions has been universally adopted. Meaningful record keeping in zoos is improving, but consistency remains a problem. Acquiring specimens of known locality is still very difficult when buying from animal dealers, and many wild-born zoo animals are of uncertain origin. Although zoo-museum collaborations occur, living collections are generally underutilized and relatively few zoo animals are used as research specimens.



In addition to research, Petzold emphasizes the potential of zoos and terrarium enthusiasts to contribute to conservation of species through captive breeding. He argues for managing populations in captivity, rather than individuals, as a means of reducing dependence on wild imports, and repatriating captive animals to support dwindling wild populations. To accomplish this, he suggests, zoos and private sector terrarium enthusiasts need to work together to pool resources and divide tasks. While there have been undeniable successes in herpetological conservation breeding projects over the last 25 years, we are far from truly managing populations in most captive reptiles and amphibians. Efforts to organize population management in US zoos are stymied by institutional policies that restrict distribution of captive born animals to the private sector, making it impossible to remove surplus offspring from the population and quickly swamping all available institutional space. These restrictive policies also make it difficult for many zoos to include private terrarium practitioners (who have, collectively, more space and time to dedicate than zoos) in cooperative breeding programs. These constraints, as well as the logistical/legal complexities of moving animals internationally, have shifted zoo conservation efforts toward range country breeding facilities where US zoos provide financial and training support.

An underlying theme of the book is zoo advocacy. Petzold clearly aims to fend off charges that zoos are philosophically corrupt and unjustifiable, and his argument centers on achievements in terrarium science and ex-situ conservation potential. The argument is convincing on its own, but lacks any mention of the primary function of modern zoos—interpretation and public education. Zoos, by definition, work in the medium of public exhibits, setting them apart from non-public research or conservation centers. While science and ex-situ conservation clearly justify keeping wildlife in captivity, the only justification for exhibiting wildlife—the activity that makes zoos unique after all—is to convey a meaningful message to an audience. Petzold certainly does not argue against the value of interpretation, but he treats meaningful education/public impact as an assumed quality of modern zoos. Unfortunately, many US zoos have shifted emphasis away from excellence in interpretation, as they have striven to be seen as conservation entities. In many institutions educational content has been shorn from graphic panels, leaving only a species name and range map. Some

major US zoos and aquariums have even removed all mention of evolution, the backbone of biological science, from interpretive programming to avoid public controversy. Interpretation is as difficult to do well as research or conservation. It deserves at least equal emphasis in an argument for zoo advocacy and desperately needs to be re-prioritized in US institutions.

The book is an English translation of Petzold's original work in German. Text is fairly readable, but some sentence structures are awkward. The content is organized into seven chapters plus a literature cited and index to scientific names. The first chapter is laced with ideological propaganda which, according to the introduction to the English edition, was required to achieve publication under the communist regime of the former German Democratic Republic. It is worth wading through the jargon, however, as this chapter also lays out a fascinating factual history of the evolving function of zoos, from the earliest known menageries—Bronze Age sacred groves and temples—through the "modern" institutions of the late 20th Century. The second chapter reviews the historical role of reptiles (and some amphibians) in zoo collections. Chapter 3 accounts for the bulk of the book and explores the results and problems with herpetological terrarium science as related to reproduction, growth and development, and nutrition. Chapter 4 suggests opportunities for research of other miscellaneous behaviors (e.g., sleep and thermoregulation). Chapter 5 explores the value of terrarium data and addresses the research advantages and limitations of captivity. Chapter 6 addresses the potential for ex-situ conservation in terrarium and zoo programs. Chapter 7 is a concluding argument that summarizes Petzold's aims for the book. I suggest reading this first as a helpful introduction.

The Lives of Captive Reptiles is a foundational book for zoo herpetologists and serious terrarium practitioners. It provides a comprehensive history of zoo and terrarium herpetological science. It speaks to some of the foundational principles of modern zoos and serves as a primer/refresher of basic ideals to which terrarium practitioners should aspire. For me it also provided back-story in the philosophy that guided the careers of a generation of zoo herpetology curators whom I have come to know and respect.

Although our knowledge of Latin American herpetology has advanced considerably over the last century, there still is a lack of appropriate field guides for most regions of South and Central America. Moreover, the majority of the existing works are written exclusively in English (rendering them incomprehensible to most Latin Americans) and cover whole countries (i.e., are not the format one would wish to carry around). Up-to-date field guides dealing with the herpetofaunas of distinct, well-studied places, apart from a handful of exceptions like La Selva (Costa Rica) or Barro Colorado Island (Panama), remain unwritten. Thus, much diversity information that may well be familiar to the scientific community remains unavailable to the people coming across this diversity every day, or to those naturalist travelers wishing to explore it.

One such gap in knowledge has recently been closed. In their book, Townsend and Wilson provide a comprehensive and detailed account of the 50 species of amphibians and reptiles currently known to occur within Cusuco National Park. Established in 1987, this reserve protects a vast stretch of isolated cloud forest in extreme northwestern Honduras. Owing to the Spanish translation by Pauline M. Kulstad, the bilingual book is able to serve as a source of information for both Hondurans and their visitors, as is the explicit intention of the authors. The price of US $45 should make it affordable for anyone interested, even if they are not lucky enough to receive First World salaries.

The book's dimensions of roughly 16 × 24 cm and 850 g allow it to easily fit into a daypack. However, before taking the book into the moist forests of Cusuco, one should consider reinforcing the binding to keep the pages together in the long run.

After separate forewords in English and Spanish, the first part of the introductory chapter briefly familiarizes the reader with Honduras and the geographic and socioeconomic setting of Cusuco National Park. As to the presented maps (Figs. 1 and 2), some more detail and especially scale bars would have been highly appreciated. In the following, the natural environment of Cusuco's

surroundings and the park itself are described in detail, including useful photographs of each forest formation, essential information on physiography, climate and vegetation, and a short summary of non-herp diversity. Especially useful for those readers who are not familiar with the area is the subsequent "visitor's guide." Here crucial hints on access (unfortunately lacking any mention of public transport), accomodation, and facilities are followed by especially useful suggestions for different ways to experience Cusuco. The encouraging section on "remote" camping is a real teaser for any adventurous mind.

The chapter on Methods and Materials comprehensively elucidates the sources of all information presented. Recent nomenclatural changes related to Cusuco's herpetofauna are explicitly addressed here.

In this way—well prepared—the reader approaches the core of the book: the chapter on Cusuco's herpetofauna. After a short summary (which erroneously states the presence of 13 lizard species—it should read 12) the authors provide separate keys for salamanders, anurans, tadpoles, lizards, and snakes. Diagnostic features are either illustrated within the keys (here, in some cases, arrows pointing out the features in question could have been inserted to help the amateur) or explained in the glossary. All keys seem practicable, permitting the identification of any of the 50 covered species if the animal in question is at hand. Preceding the respective species accounts, each group is briefly characterized. The species accounts, amounting to more than half of the book, each begin with scientific name (the advisability of the artistic italics used is debatable) followed by a brief synonymy, common name, and information on type specimen and locality. The next paragraph compares the respective species with all species from Cusuco with which it might be confused. The descriptions are short and concise, focusing on general morphology and coloration. The information on overall distribution is complemented by localities inside Cusuco where the species has been found. After notes on natural history, four indicators of the species' conservation status (distributional range, status of Cusuco's populations, Environmental Vulnerability Score, and IUCN classification) are given. Additional remarks (including short a risk assessment for the five species of venomous snakes) and specific references complete every account. All but two accounts are illustrated with photographs of predominantly good quality. Due to their position, the photos can easily be assigned to the respective species, albeit lacking figure legends. However, figure legends should have been included for other reasons, such as enabling text reference to a figure, or explaining to the amateur why one *Oedipina tomasi* has a much shorter tail than the one on the facing page.

The final chapter on the conservation of Cusuco's herpetofauna highlights the importance of the park for the conservation of the Honduran biota, developing a reasonable argumentation on the basis of its diverse, isolated, and highly endemic (nine of the 50 species are known only from the park!) herpetofauna. A summary of distribution, conservation status and population trends reveals many of the recorded species to be vulnerable or endangered. In view of Cusuco's crucial role as a reserve for a unique ecosystem, the authors point out present threats, predict future trends and set conservation priorities. It can only be hoped that their call for protection will be followed.

The book continues with a gazetteer defining the locality names used throughout the text and a comprehensive glossary which will be especially useful for readers without professional background. The glossary is followed by Acknowledgements, References, an Appendix listing known voucher specimens from Cusuco and the systematic index.

An important aspect of the present work is its bilingualism, which certainly offers the advantage of addressing more, and different, people. Notwithstanding, this concept is also likely to threaten certain qualities, be it size, format, or sheer readability. Of course the book would be handier, and probably cheaper, if restricted to one language, but luckily it has not reached excessive size or weight. Furthermore, the languages are clearly separated and the corresponding parts more or less exactly face each other owing to appropriate figure layout. Apart from missing a few expressions and the unavoidable typos (which are also found in the English part), the Spanish translation is very good and highly consistent with the English text. With these challenges satisfactorily mastered, this guide can truly serve to increase the popularity of, and the passion for, the cloud forest island of Cusuco among Hondureños as well as the gringos visiting them in search of natural beauty.

In summary, Townsend and Wilson are to be congratulated on presenting a comprehensive, reasonable and useful treatment of a unique cloud forest herpetofauna that will equally inspire and serve the professional herpetologist and the ecotourist as well as local students and future decision-makers.

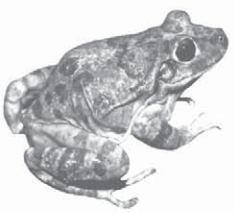
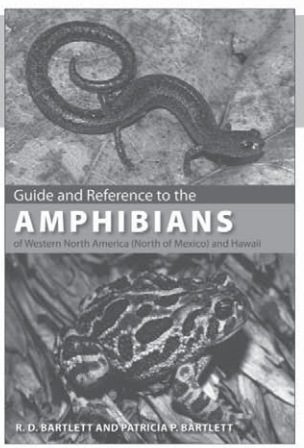
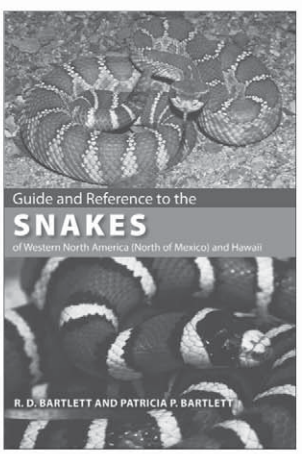
Natural History of West Indian Reptiles and Amphibians



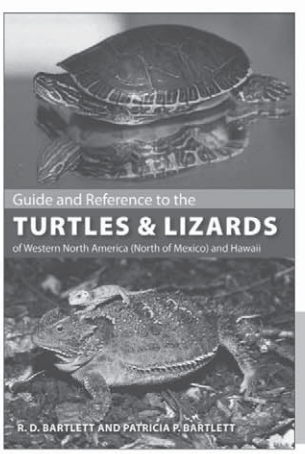
Robert W. Henderson and Robert Powell



"A state-of-the-art compendium. The West Indies is one of the hottest of the world's biodiversity hot spots and will continue to be a focus of ecological research, now invigorated by this definitive synthesis."—S. Blair Hedges, Pennsylvania State University



"The reference source that biologists interested in West Indian herpetofauna have been waiting for."—Steven Reichling, curator, Memphis Zoo, and author of *Reptiles and Amphibians of the Southern Pine Woods*



The herpetofauna of the West Indies is considered one of the richest and most vulnerable in the world. This volume summarizes the natural history of each of the more than seven hundred species of frogs and reptiles that live in the islands. Sure to be the starting point for all future research on West Indian amphibians and reptiles, it will be an essential companion to the biologist contemplating or conducting research in the area.

528 pp. | 35 b/w photos, 1 line art, 2 maps
Hardcover $85.00

New editions in our series of richly illustrated field guides to North American herpetofauna:

Guide and Reference to the Amphibians of Western North America (North of Mexico) and Hawaii

R. D. Bartlett and Patricia P. Bartlett

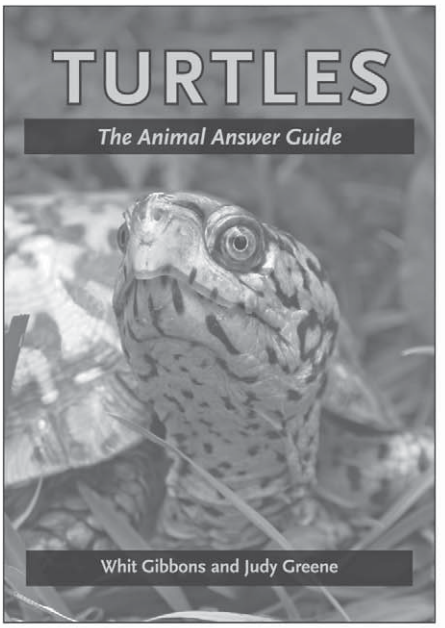
256 pp. | 159 color & 8 b/w photos
10 line drawings, 103 maps
Paperback $29.95

Guide and Reference to the Snakes of Western North America (North of Mexico) and Hawaii

R. D. Bartlett and Patricia P. Bartlett

304 pp. | 190 color & 6 b/w photos
8 line drawings, 85 maps
Paperback $29.95

Guide and Reference to the Turtles and Lizards of Western North America (North of Mexico) and Hawaii



R. D. Bartlett and Patricia P. Bartlett

336 pp. | 228 color & 8 b/w photos
8 line drawings, 125 maps
Paperback $29.95

These beautifully illustrated, full color identification guides offer a complete survey of the 146 species of snakes, 168 species of turtles and lizards, and 130 species and subspecies of amphibians that reside west of the Rocky Mountains (north of Mexico) and in Hawaii. Species are grouped alphabetically by scientific name within each order. Color photographs are accompanied by descriptive text that details the appearance, naturally occurring color morphs, behavior, range/habitat, and prey of each species—as well as species with which it may be confused.

Part of a series of guides by R.D. and Patricia Bartlett featuring color photos and descriptions of every taxon of herpetofauna in the United States and Canada!

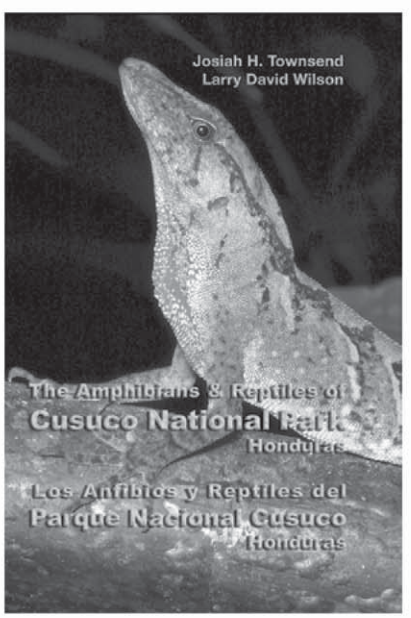
TURTLES

The Animal Answer Guide

Whit Gibbons and Judy Greene

From the palm-sized bog turtles of the United States to the great oceanic leatherbacks, turtles across the globe are admired for their persistence, patience, and resilience. They are favorites of scientific study and beloved pets throughout the world. With a friendly mix of scientific analysis and basic encyclopedic coverage, Whit Gibbons and Judy Greene discuss a broad range of turtle topics, including behavior, ecology, reproduction and development, turtle-human relationships, and the appearance of turtles in popular literature.



"Turtles, with their strange anatomy and ancient pedigree, never cease to amaze people. Whit Gibbons and Judy Greene have been faced with every conceivable question about the 300 or so species of these endearing reptiles, and in this book they have succeeded splendidly in coming up with the answers."

—Peter C. H. Pritchard,
Chelonian Research Institute

With attractive photographs and an intuitive question-and-answer format, Gibbons and Greene answer more than 100 common questions about these remarkable creatures. Readers who want answers to specific questions or just want to expand their knowledge about these unique and interesting animals will find the information they seek in this essential reference.

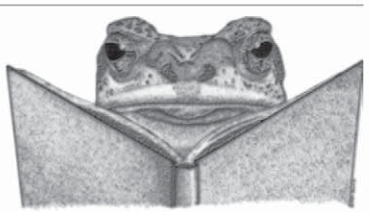
The Amphibians & Reptiles of Cusuco National Park, Honduras

Los Anfibios y Reptiles del Parque Nacional Cusuco, Honduras



Josiah H. Townsend and Larry David Wilson

Cusuco National Park in northeastern Honduras is home to 50 species of amphibians and reptiles, nine of which are endemic to the park. This book, in English and Spanish, is an in-depth guide to the park's herpetofauna.

Specifications: xiv, 322 pages, 6 x 9 inches. Hardcover (ISBN: 978-1-932871-12-8) $44.95 + postage.

Happy 100th Birthday

to

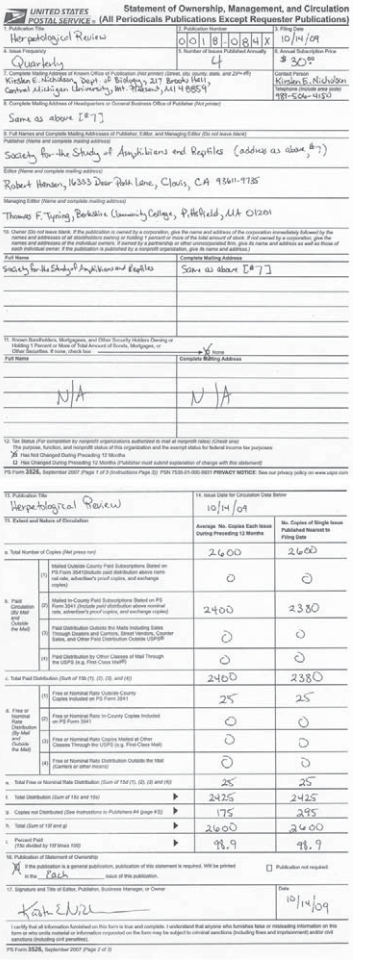
Dr. Wilmer W. Tanner

(Born December 17, 1909)

from

SSAR

PHOTO COURTESY OF KRAIG ADLER



In appreciation for many years of service to the science and people of herpetology. Aside from his research activities and numerous publications, one of Dr. Tanner's signal contributions was his guidance of The Herpetologists' League through financially turbulent times. He also served as Editor of *Herpetologica* from 1960 through 1967. Dr. Tanner continues to make weekly visits to his office at the Monte L. Bean Life Science Museum at Brigham Young University.

Cover Images for *Herpetological Review*

We are looking for photographic images to appear on future covers of *HR*. To be considered, preferred images should have the following qualities:

- Should be technically superior photographs (e.g., composition, lighting, etc., should be excellent; subject must be in focus).
- Should be taken in vertical format, or, if in landscape format, permit cropping to achieve a vertical orientation.
- Should be based on film or digital media; if the latter, the native resolution must be sufficiently high to permit cropping and/or enlargement to print publication quality (many "point-and-shoot" digital cameras do not produce image files with sufficient resolution for print publication).
- Preference will be given to images that depict poorly known species. These could include recently described taxa or species for which a color illustration has never been published.
- Preference will be given to images that communicate some aspect of the biology of the organism (e.g., predation, feeding, courtship, crypsis).

Images for consideration should be submitted as low-resolution jpg or pdf files. Do not send full resolution images via email. All submissions or questions should be directed to the Editor (herpreview@gmail.com).

UNITED STATES POSTAL SERVICE — Statement of Ownership, Management, and Circulation (All Periodicals Publications Except Requester Publications)

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.php>

Reprints and Page Proofs

Reprints of notes or articles published in ***HR*** may be ordered through EZReprints (EzReprint@odysseypress.com), an online reprint odering system. Authors will receive email notification as the issue goes to press. Page proofs are sent electronically to authors of all articles, book reviews, and obituaries, but are not sent for natural history notes or geographic distribution notes. Proofs are sent as pdf files approximately 2–4 weeks prior to publication.

Advertising

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR web page (http://www.ssarherps.org/pages/HRinfo.php).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Central Michigan University, Department of Biology, 217 Brooks Hall, Mt. Pleasant, MI 48859, USA. Periodicals postage paid at Mt. Pleasant, MI 48859 and at additional mailing offices. All rights reserved. No part of this periodical may be reproduced without written permission of the Editor, except that authors and their agents are permitted to reproduce and distribute their own articles and notes. **POSTMASTER:** Send address changes to *Herpetological Review*, Allen Press, Inc., P.O. Box 1897, Lawrence, KS 66044, USA. Regarding missing or damaged issues, please notify *Herpetological Review*, Allen Press, Inc., P.O. Box 1897, Lawrence, KS 66044, USA (tel. 785/843-1234 or e-mail: herps@allenpress.com).

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: http://www.ssarbooks.com/.

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available for purchase from the SSAR Bookstore (http://www.ssarbooks.com/). Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 840		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)		$35
INCOMPLETE SET: NUMBERS	1 – 190	$75
	191 – 410	$85
	411 – 840	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com. Online orders at: http://www.ssarbooks.com/.

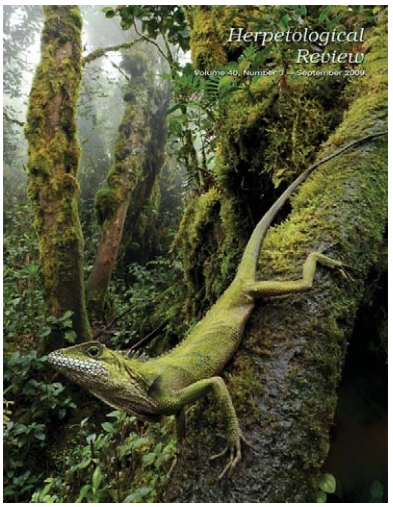
SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology,* and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.



To join SSAR or to renew your membership, please visit the secure online Allen Press website via this link:

http://www.ssarherps.org/pages/membership.php

Future Annual Meetings

2010 — Providence, Rhode Island, 7–12 July (with ASIH, HL)
2011 — Minneapolis, Minnesota, dates TBA (with ASIH, HL)
2012 — Vancouver, British Columbia, dates TBA (with ASIH, HL, WCH)

About Our Cover: *Gonocephalus robinsonii*

Of the 28 species of agamid lizards in Peninsular Malaysia and its associated archipelagos, only six occur in the genus *Gonocephalus* (Grismer 2008. Zootaxa 1860:28–34; Wood et al. 2009. Zootaxa 2012:28–46). All *Gonocephalus* in Peninsular Malaysia are diurnal, arboreal species and most show significant degrees of sexual dimorphism. *Gonocephalus robinsonii* is an arboreal, diurnal, upland species restricted to hill dipterocarp forests between 700 and 1700 m in elevation. This strange-looking lizard goes well with the mysterious lichen and moss-covered forests it inhabits. During the day, individuals are most commonly seen on the sides of both large and small tress, usually less than three meters above ground. Juveniles seem to be more active than adults and will flee up the trunk of a tree at the slightest provocation, whereas adults generally tend to hold their position. At night, all age classes can be found sleeping on the branches of tree ferns as well as the vertical branches of smaller trees as high as 9 m above ground. Breeding generally coincides with the winter monsoons with hatchings appearing near the end of the season. *Gonocephalus robinsonii* occurs in at least two different isolated mountain ranges: the extensive Banjaran Titiwangsa in the west that runs nearly the entire length of the peninsula, and the much smaller Gunung Tahan in the east.

The cover photo was taken by **L. Lee Grismer**, professor of biology at La Sierra University, Riverside, California. Grismer has been working intensively in Peninsular Malaysia since 2003 and in the last six years, his team has discovered and described over 25% of this region's known lizard fauna, describing more species than had been identified during the previous century. They have also discovered several new species of frogs and snakes. Grismer's latest book, *The Lizards of Peninsular Malaysia, Singapore, and the Adjacent Archipelagos*: *Their Description, Distribution, and Natural History*, is scheduled for publication in early 2010 and will be patterned after his earlier book on the herpetofauna of Baja California.

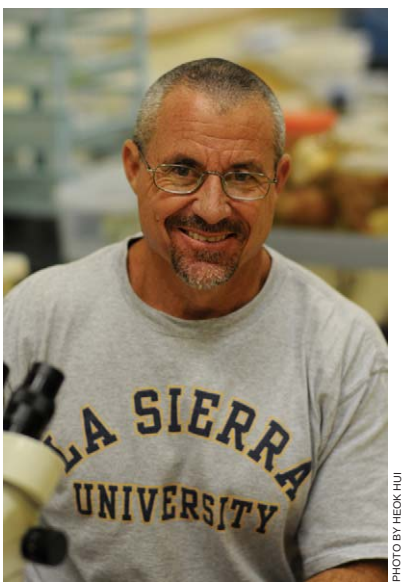


PHOTO BY HEOK HUI

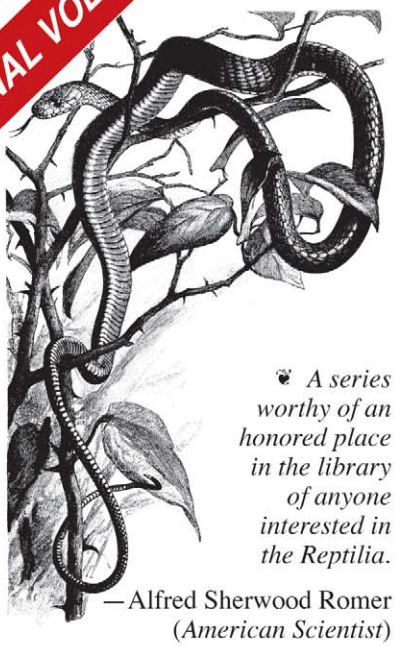
The cover photo was recorded at Cameron Highlands, Pahang, with a Nikon D300 and a Sigma 14mm lens. The scene was metered to ambient light at ISO 200, and recorded using fill flash (Nikon SB20) set to -3EV at f22. According to Grismer, "What really made it work was after I began shooting, the clouds rolled in, surrounding the trees in mist, thus really adding a 'cloud forest' feel to the shot."

SSAR BUSINESS

Journal of Herpetology Receives Award: Ranked Among Top 100 Journals in Biology and Medicine in the Past 100 Years

In conjunction with the Special Libraries Association's Centennial, the BioMedical & Life Sciences Division conducted a poll to identify the 100 most influential journals of Biology & Medicine worldwide over the last 100 years. The division was led in 2008 by Chair John Tebo, University of Cincinnati, and in 2009 by Chair Jean Crampon, University of Southern California. Three panels consisting of three experts each were recruited from the DBIO membership. Each panel composed a series of voter preference questions comparing journals in categories of biology or medicine that fell within its areas of expertise.

The *Journal of Herpetology* was considered by the Natural History Panel and competed in the category of "Vertebrate Biology—Reptiles and Amphibians." It surpassed some estimable competitors to make it into the top 100 journals. The other top journals recognized include *Nature*, *Science*, *Ecology*, *Animal Behavior*, and *Proceedings of the Royal Society (Biology)*. SSAR was represented at a luncheon and awards celebration in Washington, DC on 16 June 2009 by Past-President, Roy McDiarmid, and Board Member, Kevin de Queiroz.



SSAR is pleased to recognize the longstanding commitment

SSAR President Brian Crother is flanked by Matt Parris (Editor, *Journal of Herpetology*, left) and Kevin de Queiroz (SSAR Board Member, right), after sharing the Top 100 Journals award during the SSAR Board Meeting in Portland.

FINAL VOLUME

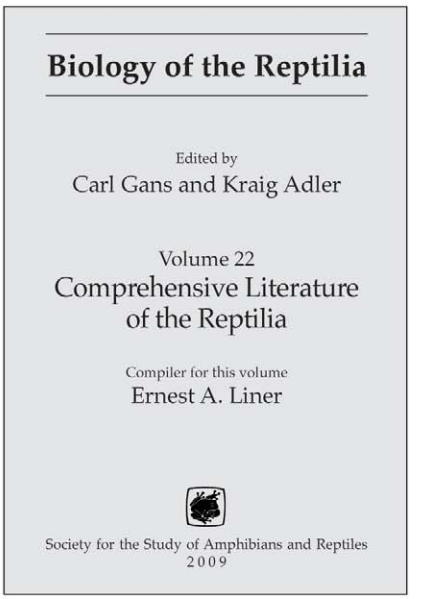
The Final Volume in This Classic Series from the Society for the Study of Amphibians and Reptiles

BIOLOGY OF THE REPTILIA

THIS CELEBRATED SERIES, NOW EXTENDING TO 22 VOLUMES, HAS BEEN WIDELY acclaimed as the definitive resource on reptilian biology. From the first volume in 1969, the distinguished contributors to this series have included an international group of more than 150 experts in their respective fields. Each volume consists of multiple chapters summarizing the state of our knowledge, laying groundwork for future research, and providing an in-depth guide to the relevant literature. All volumes are fully illustrated with figures, graphs, and extensive tables of information. Each text volume has both subject/species and author indices. Volume 22 comprises the comprehensive bibliography and cross-referenced index to the entire 21-volume series, which includes more than 22,000 references. SSAR has been proud to assume responsibility for this classic series and to offer clothbound volumes at affordable prices.

❦ *A series worthy of an honored place in the library of anyone interested in the Reptilia.*

—Alfred Sherwood Romer (*American Scientist*)



❦ *A broad, unified treatment of everything concerning the structure and the life of living reptiles.*

—Benedetto Lanza (*Scientia*)

❦ *There has been no work comparable to this in any language.*

—Garth Underwood (*British Journal of Herpetology*)

General Editor: Carl Gans
Co-editors of Previous Volumes:
***Morphology* (nine volumes):** Kraig Adler, Angus d'A. Bellairs, Abbot Gaunt, Thomas S. Parsons
***Physiology* (five volumes):** David Crews, William R. Dawson, K. A. Gans, F. Harvey Pough
***Ecology and Behavior* (two volumes):** Raymond B. Huey, Donald W. Tinkle
***Neurology* (three volumes):** R. Glenn Northcutt, Philip S. Ulinski
***Development* (two volumes):** Frank Billett, Paul F. A. Maderson

VOLUME 22: COMPREHENSIVE LITERATURE OF THE REPTILIA

• Edited by Carl Gans and Kraig Adler • Compiled by Ernest A. Liner •

This volume, the final one in the *Biology of the Reptilia* series, covers a vast literature on turtles, crocodilians, lizards, snakes, and tuatara. It includes their behavior, development, ecology, morphology, neurology, and physiology, as well as their evolution and systematics. It is a synthesis of the 22,255 literature references included in 136 chapters by 169 authors over a 40-year period, with links to the chapters in which the reference appeared and an extensive cross-referenced subject index. At 1,400 pages, it represents **the most extensive compilation and index to the literature of the Reptilia ever undertaken** and probably the most comprehensive single work on the topic that will ever again be made available in printed form. Every effort has been made to correct references that were originally in error and to provide citations for those that were listed as "in preparation," "in manuscript," or "in press." **This huge volume will be an essential reference to biologists, herpetologists, conservationists, zoo curators, reference librarians, government personnel, and veterinarians, among others.**

Specifications: Volume 22, 1,400 pages (ISBN 978–0–916984–80–9). Clothbound with dust jacket. **To be published: December 2009.**

***Price*:**	***Shipping cost*:**
SSAR members *before 31 March 2010* . . . . . US$95	Shipping will be charged at cost.
Institutions and Non-members . . . . . US$130	Insurance is extra, on request.

Send orders to: Breck Bartholomew, SSAR Publications Secretary, P. O. Box 58517, Salt Lake City, Utah 84158–0517, USA (*telephone*: area code 801, 562–2660; *e-mail*: ssar@herplit.com). Make checks payable to "SSAR." Overseas customers may make payment in USA funds using a draft drawn on American banks or by International Money Order. All persons may charge to MasterCard, American Express, Discover Card, or VISA (please provide account number and expiration date). SSAR membership details and a complete list of all Society publications can be obtained on request to the Publications Secretary (address above). For details, check the Society's webside at www.ssarherps.org.

NOTE: Copies of Volumes 19–21 (Morphology G–I) are available from SSAR. SSAR did not publish and does not sell volumes 1–18 in the series.

to excellence by the editors of the *Journal of Herpetology* from its inception: Kraig Adler (1958–1963), James A. MacMahon (1964), Corson Jay Hirschfeld (1965–1967), J. P. Kennedy (1968–1979), Rodolfo Ruibal (1980–1989), Samuel S. Sweet (1990–1992), Richard A. Seigel (1993–2000), Brian K. Sullivan (2001–2005), Geoffrey R. Smith (2006–2008), Matthew J. Parris (2009–present). The award is also a credit to the associate editors, editorial board members, and hundreds of anonymous reviewers who have served over the 52-year existence of the journal.

Consult the complete list of awardees at:

http://units.sla.org/division/dbio/publications/resources/dbio100.html

2008 Official Names List Now Available Online Free

The newest edition of *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico*, the official names list adopted by the American Society of Ichthyologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles, is now available as a free download from the SSAR website:

http://ssarherps.org/pages/HerpCommNames.php

Kennedy Student Award 2009

The Kennedy Award Committee (Carl Anthony, Bill Lutterschmidt, Terry Schwaner, Lynnette Sievert, Chair) has completed its work for Volume 42 of the *Journal of Herpetology*. The Committee has selected "Preference for Local Mates in a Recently Diverged Population of the Lesser Earless Lizard (*Holbrookia maculata*) at White Sands" by Erica Bree Rosenblum (Vol. 42:572–583). The Kennedy Award carries with it a cash prize of US $200 or the winner's selection of any SSAR publications valued at twice that amount.

The committee invites all student members of the Society to submit their work to the Journal, and encourages members who supervise the work of students to draw this award to the attention of those students.

Dean E. Metter Memorial Award for 2009

There were 25 proposals submitted this year for the Dean E. Metter Memorial Award. The proposals were all of high quality; two stood out from the others. The committee requested permission from President Crother to make two awards this year and that request was granted.

The first award winner is Benjamin Jellen of Saint Louis University. He is a Ph.D. student in the Department of Biology working with Robert Aldridge. His proposal is entitled "Pre-and post-copulatory determinants of reproductive success in Missouri northern watersnakes (*Nerodia sipedon*)." The research attempts to show how these snakes communicate using pheromones and how this relates to male and female reproductive success.

The second award winner is Jeanine Refsnider. Her proposal deals with Painted Turtles (*Chrysemys picta*) and is designed to determine whether local adaptations to nest site choice are more genetically or environmentally driven ("Can maternal nest-site choice compensate for the effects of global climate change on reptiles with temperature-dependent sex determination? A common garden experiment using a model species"). She is working in Fred Janzen's laboratory in the Department of Ecology, Evolution, and Organismal Biology at Iowa State University.

NEWSNOTES

Panama Amphibian Rescue and Conservation Project

Recognizing that Panama's rich diversity of amphibians is an important natural treasure with significant direct, cultural, biomedical, ecological and existence values that warrants protection from extinction, a group of organizations came together to respond to the crisis. Africam Safari Park (Mexico), Cheyenne Mountain Zoo (Colorado), Defenders of Wildlife (Washington DC), the Smithsonian National Zoological Park (Washington DC), the Smithsonian Tropical Research Institute (Panama), Zoo New England (Massachusetts) and Houston Zoo (Texas) have pooled their energy and resources, collectively pledging more than $750,000 in cash and in kind over the next three years to the Panama Amphibian Rescue and Conservation Project.

The Project will consist of three distinct and complementary parts: 1) the ongoing operation of El Valle Amphibian Conservation Center (EVACC) in Western Panama, run by the Houston Zoo; 2) the amphibian chytrid cure research program to be initiated at the National Zoo in collaboration with Vanderbilt University; and 3) the construction and operation of the new Summit Park Amphibian Rescue Center in Panama. One "amphibian rescue pod" which is a biosecure, modified shipping container that will house the first rescued species from Eastern Panama has already been established.

Please find out more about this project at:

http://www.amphibianrescue.org/

MEETINGS

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (HerpReview@gmail.com) well in advance of the event.

2–4 October 2009—Symposium on *Anolis* Biology, Harvard University, Cambridge, Massachusetts, USA. Information: http://anolis.oeb.harvard.edu.

17 October 2009—Texas Herpetological Society Fall Meeting and Lizard Symposium, Brazos Center, Bryan, Texas, USA. Information: http://www.thehibbitts.net/THS/.

17–19 October 2009—Gaffney Chelonian Fossil Symposium, Drumheller, Alberta, Canada. Information: http://www.tyrrellmuseum.com/events/turtlesymp09.php

26–28 February 2010—35th Annual Desert Tortoise Council Symposium, Ontario, California, USA. Information: http://www.deserttortoise.org/symposia.html

22–24 April 2010—57th Annual Meeting, Southwestern Association of Naturalists, Llano River Field Station, Junction, Texas, USA. Information: http://www.biosurvey.ou.edu/swan/annualm10.html

7–12 July 2010—Joint Meeting of Ichthyologists and Herpetologists (ASIH / HL / SSAR), Providence, Rhode Island, USA. Information: http://www.dce.k-state.edu/conf/jointmeeting/

21–24 July 2010—33rd Annual International Herpetological Symposium, Tucson, Arizona, USA. Information: http://www.kingsnake.com/ihs/

CURRENT RESEARCH

The purpose of Current Research is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, Joshua Hale or Ben Lowe; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can be found at: http://www.herplit.com/contents.

Impacts of Climate Change on Tropical Lizard Communities

As tropical lizard taxa occurring in forested habitats are adapted to narrow temperature intervals and are functionally thermoconformers, slight elevations in mean temperature due to climate change may disproportionately affect them. To gain insight into this phenomenon, the authors first accumulated body temperature, thermal maximum, minimum, and optimum, maximum latitude, habitat type (open or forested), thermoregulation method (basking or not), and phylogenetic relationship data for 66 species (determined in previous studies) and performed a meta-analysis in order to reveal correlations between the physiological traits and the ecological, behavioral, distributional, and phylogenetic information. Second, fine-scale environmental and physiological data for diurnal Puerto Rican *Sphaerodactylus* and *Anolis* (four and two species, respectively) were used to determine the effect predicted climate change will have on lizards occupying different environments. The meta-analysis reveals that some tropical taxa indeed have low thermal maxima relative to the environment in general and are restricted to cool microclimates. Furthermore, the study of the Puerto Rican taxa reveals that these thermoconformers are already operating at temperatures in excess of their thermal maxima and likely will be pushed beyond their thermal tolerance with predicted temperature increases. This study further substantiates that the effects of climate change will be multifarious and will impact every sector of the globe.

Huey, R. B., C. A. Deutsch, J. J. Tewksbury, L. J. Vitt, P. E. Hertz, H. J. Álvarez Pérez, and T. Garland Jr. 2009. Why tropical forest lizards are vulnerable to climate warming. Proceedings of the Royal Society B 276:1939–1948.

Greater Species Richness in the Tropics: Extinction, Speciation, or Historical Biogeography?

Traditionally, the elevated species richness in the tropics has been explained by higher rates of speciation or lower rates of extinction relative to temperate regions. However, recent research has revealed that in some systems, rates of speciation and extinction are comparable in the two regions and that the higher species richness in the tropics is a result of the lineages of interest having occupied these regions for a longer period of time. In this study the authors aimed to determine if this was the case with ranid frogs. In addition to presenting a new phylogeny of the family Ranidae, divergence times and ancestral geographic distributions were estimated using the software BEAST and Mesquite, respectively. A simple regression revealed a highly significant correlation between regional diversity and cumulative time of lineage presence in a region. A regression of diversification rate of clade against latitudinal midpoint revealed a weak positive correlation, with higher latitudes exhibiting a slightly higher diversification rate, which further demonstrates that higher species richness in the tropics is not due to higher speciation rates or lower extinction rates in that region. This study reiterates the importance of taking historical biogeography into account when trying to explain patterns of biodiversity.

Wiens, J. J., J. Sukumaran, R. A. Pyron, and R. M. Brown. 2009. Evolutionary and biogeographic origins of high tropical diversity in Old World frogs (Ranidae). Evolution 63:1217–1231.

Documenting Salamander Declines in the Neotropics

Anuran declines have received much deserved attention; however, in some parts of the globe, salamander species are disappearing at an equally alarming rate. In this paper the authors compare recent and historical salamander abundance data from several sites in southern Mexico and Guatemala, many of which still contain abundant suitable habitat. Analyses revealed that many taxa have experienced precipitous declines and local extirpations, with very

few species maintaining or increasing in abundance. These findings span Mexico's Isthmus of Tehuantepec, across which there is a complete turnover in the salamander biota. Analyses further revealed that these population declines and extirpations seem to disproportionately affect upper cloud forest and high elevation species. Additionally, within these habitats, species that utilize arboreal microhabitats seem to be relatively unaffected while the terrestrial microhabitat specialists are experiencing most of the population declines and extinctions. Interestingly, the low-elevation species disproportionately utilize arboreal microhabitats. Finally, based on records from southern Mexico, the timing of the declines seems to coincide with dramatic declines in anuran species in the region, suggesting that chytridiomycosis may have played a role in the decline of these salamander species as well.

ROVITO, S. M., G. PARRA-OLEA, C. R. VÁSQUEZ-ALMAZÁN, T. J. PAPENFUSS, AND D. B. WAKE. 2009. Dramatic declines in neotropical salamander populations are an important part of the global amphibian crisis. Proceedings of the National Academy of Sciences 106:3231–3236.

Quantifying the Chameleon's Ability to Adjust UV Exposure in Response to Low Vitamin D_3 Diet

Vitamin D_3 is a hormone essential to most vertebrates including squamates; however, excessive vitamin D_3 is fatal. Therefore, animals should be expected to exhibit behaviors that regulate D_3 levels. Previous studies have determined the optimal level of UVB exposure (necessary for the production of D_3) for chameleons and have shown that they have the ability to behaviorally compensate for a low D_3 diet by increasing UVB exposure time. However, these studies failed to quantify the accuracy and precision of this ability. To address this question, the authors of this study placed six Panther Chameleons (*Furcifer pardalis*) in outdoor enclosures and divided them into high and low D_3 diet treatments. Daily movements were monitored via video camera. Using models soaked in provitamin D_3 (a chemical vitamin D_3 precursor that converts to vitamin D_3 when exposed to UVB), the recorded movements were replicated the following day to allow for quantification of the level of D_3 production. These experiments revealed the chameleon's ability to behaviorally compensate for different levels of vitamin D_3 to be both highly precise and accurate, with low D_3 diet treatment lizards maintaining optimal levels of D_3 via increased UVB exposure and those in the high D_3 diet treatment similarly maintaining optimal levels of D_3 by moderating UVB exposure.

KARSTEN, K. B., G. W. FERGUSON, T. C. CHEN, AND M. F. HOLICK. 2009. Panther chameleons, *Furcifer pardalis*, behaviorally regulate optimal exposure to UV depending on dietary vitamin D_3 status. Physiological and Biochemical Zoology 82:218–225.

Malagasy Anuran Diversity Greatly Underestimated

Madagascar, together with the oceanic islands of the Indian Ocean, is considered one of 34 biodiversity hotspots by the organization Conservation International and possesses a unique herpetofauna. Malagasy anurans are particularly diverse and unique, constituting five evolutionary lineages (including two endemic families) and exhibiting 100% species endemicity. One of the primary goals of conservation groups is to document the biodiversity within these hotspots before it is too late. With this goal in mind, the authors conducted surveys and analyses with the goal of assessing Malagasy anuran diversity. A combination of mitochondrial sequence, vocalization, morphological, and geographic data were accumulated for ca. 2850 specimens. Molecular analyses were performed to identify divergent lineages within currently recognized species. If these lineages were found to be morphologically or bioacoustically divergent, they were categorized as Confirmed Candidate Species (CCS); if no morphological or bioacoustic data were available, they were classified as Unconfirmed Candidate Species (UCS). These analyses revealed a veritable cornucopia of undescribed diversity. Assuming the CCS and UCS categories reflect legitimate species, this study raises the number of species occurring in Madagascar from 244 to 465 (an increase of 90.6%). These results reiterate how much of the world's diversity remains to be discovered and emphasizes the importance of quantifying the biodiversity of hotspots.

VIEITES, D. R., K. C. WOLLENBERG, F. ANDREONE, J. KÖHLER, F. GLAW, AND M. VENCES. 2009. Vast underestimation of Madagascar's biodiversity evidenced by an integrative amphibian inventory. Proceedings of the National Academy of Sciences 106:8267–8272.

Box Turtle Abscesses Heal Themselves

Cranial abscesses are a frequently observed phenomenon in box turtles (*Terrapene*). While standard procedures exist for treating this disease in captive animals, the final result of such abscesses in nature has remained uncertain. The author reports on findings resulting from tracking 144 Eastern Box Turtles (*T. carolina*). Twenty cases of aural abscesses were recorded over the course of a decade. Of these, fifteen cases healed naturally and five required researcher-induced amputation (after turtle exhibited obvious weight loss). This is the first evidence in support of the hypothesis proposing that these abscesses spontaneously disappear in nature.

BELZER, W. R. 2008. Spontaneous resolution of aural abscesses in the eastern box turtle, *Terrapene carolina carolina*. Journal of Herpetological Medicine and Surgery 18:64–66.

Piscivory Correlated with Morphological Evolution in Natricine Snakes

The various species of natricine snakes exhibit the full spectrum of percentage of diet composed of fish. However, much remains to be learned about how morphology and feeding performance are related to obligate piscivory in these snakes. The authors of this study accumulated data on quadrate bone length (as they hypothesize an increase in quadrate length would allow snakes to more easily feed on odd-shaped prey items), fish-eating performance, and fraction of fish in diet, and incorporating accepted hypotheses of evolutionary relationships, tested for convergent evolution in natricines. Experiments ascertaining feeding performance involved feeding snakes fish and timing the event. Results revealed that increased feeding performance was indeed correlated with elongation of the quadrate when the prey is fish. Furthermore, an ancestral state reconstruction suggested that all major lineages were ancestrally generalists; specialization on fish or non-fish evolved several times quickly and recently within those lineages. Finally, an independent contrasts analysis confirmed increased quadrate length is highly correlated with increased percent fish in diet and scales allometrically with increased head length. This fascinating example of convergent evolution suggests that dietary specialization can have dramatic effects on all aspects of an organism's biology.

VINCENT, S. E., M. C. BRANDLEY, A. HERREL, M. E. ALFARO. 2009. Convergence in trophic morphology and feeding performance among piscivorous natricine snakes. Journal of Evolutionary Biology 22:1203–1211.

Where Does the Ring End? Testing Biogeographic Hypotheses in *Ensatina*

Ensatina salamanders have served as the textbook example of a "ring species" for decades. Historically, it has been suspected the terminus of this ring occurred in the mountains of southern California. However, geologic data suggests that a significant barrier to dispersal existed in coastal central California, as the southern Coast Range was first an island chain, then (once joined with the mainland) separated from the northern Coast Range by the outlet of the inland sea at what is now Monterey. Under this scenario, dispersal south along the Sierra Nevada, west to the coast, then north to Monterey would be the more likely dispersal scenario and Monterey should be the terminus of the ring. If the terminus is in the south, lineages on either side of Monterey would be closely related and lineages in the mountains of southern California would be deeply divergent. If the terminus is in Monterey, the opposite would be true. To evaluate these two hypotheses, a phylogeographic analysis was conducted using mitochondrial DNA sequences from samples obtained from throughout the distribution of the species. An analysis of the credible set of trees revealed a sister-species relationship of the two southern California lineages (and the Monterey terminus hypothesis) could confidently be rejected. Alternatively, greater than 99.9% of the trees were consistent with a southern California terminus and find lineages north and south of Monterey to have a sister relationship. Interestingly, a molecular clock analysis revealed that this coastal California clade originated no sooner than nine million years ago, vastly predating the unification of the Coast Range.

KUCHTA, S. R., D. S. PARKS, R. LOCKRIDGE MUELLER, AND D. B. WAKE. 2009. Closing the ring: historical biogeography of the salamander ring species *Ensatina eschscholtzii*. Journal of Biogeography 36:982–995.

Venom Potency Correlated with Diet in *Echis* Vipers

Given the different physiologies of different prey items, it would follow that major dietary changes would lead to venom evolution in snakes. This hypothesis was tested in snakes of the genus *Echis*. Previous work suggests that *Echis* is made up of four species groups. Mitochondrial and nuclear sequence data were generated for representatives of each of the four lineages and a Bayesian phylogenetic analysis was performed to reveal the relationship of these lineages to each other. Additionally, data were accumulated on diet and aspects of the venom (LD_{50} and time to death) when administered to scorpions. Placing dietary preference on the resulting tree, it was discovered that the ancestral condition for the genus is an arthropod diet, with one *Echis* lineage secondarily evolving a rodent diet. Additionally, a correlation was revealed between percentage of arthropods in diet and toxicity (LD_{50}) to scorpions. Interestingly, time to death did not appear to be correlated with arthropod diet, suggesting that venom conservation alone is the target of selection.

BARLOW, A., C. E. POOK, R. A. HARRISON, AND W. WÜSTER. 2009. Coevolution of diet and prey-specific venom activity supports the role of selection in snake venom evolution. Proceedings of the Royal Society B 276:2443–2449.

Lampropeltine Relationships Resolved

Hypotheses regarding the evolutionary relationships and the resulting taxonomy of the North American lampropeltine snakes have been in flux recently. Using mitochondrial and nuclear DNA sequence data, the authors performed a comprehensive phylogenetic analysis of this group using Old World rat snakes for outgroups. This analysis revealed a monophyletic Lampropeltini and clades largely concordant with morphology (including monophyletic *Pantherophis* and *Pituophis*), upon which the original taxonomy was based. Three taxa (*Arizona*, *Rhinocheilus*, and *Cemophora*) were revealed to be closely allied with *Lampropeltis* (king snakes); a fourth (*Stilosoma*) was recovered as highly nested within *Lampropeltis*. Furthermore, several novel relationships were revealed

within *Lampropeltis* and one species (*L. triangulum*) was found to be comprised of no fewer than two deeply divergent lineages. Finally, a molecular clock analysis found the origin of Lampropeltini to be concordant with an initial dispersal into North America via Beringia.

PYRON, R. A., AND F. T. BURBRINK. 2009. Neogene diversification and taxonomic stability in the snake tribe Lampropeltini (Serpentes: Colubridae). Molecular Phylogenetics and Evolution 52:524–529.

Australian Cane Toads More Susceptible to Ant Attack than Native Anurans

As invasive species originated in and were adapted to different environmental conditions, they should be expected to exhibit vulnerabilities to certain dangers not shared with native animals, regardless of overall successfulness in the new environment. In this study, the authors investigated the susceptibility of Cane Toads (*Bufo* [*Rhinella*] *marinus*) to ant attack relative to native anurans. Metamorphic Cane Toads, *Litoria* (five species), and myobatrachids (two species), all of which co-occur in Australia's Northern Territory, were measured for various morphometric traits, sprint speed performance, and response to a simulated ant attack. Daily activity patterns were documented both in captivity and in the field for meat ants (*Iridomyrmex* spp.; common predatory ants in ecosystems of interest) and in captivity for the anurans. Furthermore, ants were introduced to anuran terraria and interactions were recorded. Finally, bait was placed in specific microhabitats within enclosures to look for variation in detectability; bait was also placed in the center of a piece of paper laden with species-specific anuran secretions and ants were introduced to terraria to determine how the ants responded. The Cane Toads were found to come into contact with ants more frequently than the other anurans because of their diurnal activity and preferred, exposed microhabitats. Additionally, they failed to anticipate an impending attack more frequently than native frogs and the toad's short hops and frequent reliance on crypsis increased their susceptibility to ant attack. Ants failed to elicit a species-specific response to the anuran secretions. Now that they have been identified, these vulnerabilities could perhaps be employed in cane toad eradication projects.

History of Early French Herpetology. Part I: The Reptile Menagerie of the Museum of Natural History in Paris

JAMES B. MURPHY
Department of Herpetology, Smithsonian National Zoological Park
3001 Connecticut Ave., N.W., Washington DC 20008, USA
e-mail: jbmurphy2@juno.com

Today the Jardin des Plantes is interesting to visit purely on an historical perspective as it has two separate buildings devoted to reptiles. The most interesting dates from the Victorian era, while the "new" one looks as if it was constructed in the 1930s. The Victorian building still retains and uses the original ornate legged, glass-fronted, mahogany reptile cases and marble-walled crocodile pits. To see the reptile cages here is to step back in time and view the first dawning of modern herpetoculture.

—Jon Coote, 2001

The Site.—The Ménagerie, called Les Jardin des Plantes, of the Museum of Natural History in Paris (la ménagerie du Muséum d'histoire naturelle) was created in 1793 and was the first of the national menageries. Prior to the inception of the Jardin des Plantes, practically all exotic animal collections were held by kings, queens, rulers, and other powerful political figures. During the French Revolution, the Jardin des Plantes was appropriated by the revolutionaries from the Jardin du Roi in Versailles. In 1793 this Royal Menagerie was renamed Jardin des Plantes and moved from Versailles to Paris. In Lewis Pyenson and Susan Sheets-Pyenson's book, *Servants of Nature. A History of Scientific Institutions, Enterprises, and Sensibilities*, they describe it this way: "The splendors of Versailles, including its extensive gardens and menagerie, became one of the most powerful symbols of the ancien régime to the revolutionaries of the 1790s. In the context of this upheaval, a Jacobin mob set out from Paris to liberate the animals, resulting in the senseless slaughter of most of them. The surviving animals went to the Jardin des Plantes in Paris, to serve as the nucleus of a new national collection. Other animals were added that had been seized from private menageries and circuses" (p. 166). It was the first truly public collection. If one compares it to the Schönbrunn Menagerie in Vienna, Austria, the latter was a collection that had enclosures surrounded by a central viewing pavilion, designed to provide views of the animals only to those privileged enough to be inside it. The Jardin conversely has broad walkways and avenues, down which ordinary people could, and still can, stroll to admire the animals. This design reflects its unique origin—a royal menagerie appropriated by the people for the people. Truly an important change in zoo history!

The Jardin is a short walk from the Museum so it is likely that herpetologists from both places regularly interacted with each other. In fact, it is reasonable to assume that herpetologists stationed at the museum would dash over to the menagerie whenever a new shipment of interesting live amphibians and reptiles arrived. In the mid-18th and early 19th century, three famous herpetologists were associated directly or indirectly with the menag-

erie: Georges-Louis Leclerc compte de Buffon (Fig. 1), Baron Georges Cuvier (Fig. 2), and Count de Lacepède (Fig. 3). The rich history as a center for experimental zoology is detailed extensively by Gustave Loisel (1912) and other references are provided below.

The Terrarium, from 1839 under the charge of André Marie Constant Duméril, was a separate section in the old monkey house, which housed 80 reptiles of 24 species, amphibians, fishes and insects. A common practice in Europe was to encourage travelers to secure specimens for collections; in some cases, written instructions were given to the collectors.

Built in the 1870s, the Menagerie's reptile building today has a large aquatic exhibit which houses an impressive collection of crocodilians. At one end of the building, large tortoises are on display. Madagascan reptiles are well represented. Several extensive graphic displays with lifelike models of reptiles are situated throughout the building. Some of the larger enclosures are being remodeled. In the newer Vivarium building located near the reptile building, smaller amphibians and reptiles are represented in naturalistic settings.

Publications.—Between 1834–1854, Constant Duméril (Fig. 4), his son Auguste Henri André Duméril (Fig. 5), and Gabriel Bibron (Fig. 6) published the monumental multi-volume work called *Erpétologie générale, ou, Histoire naturelle complète des reptiles*. In one of the volumes—the Atlas—are 120 nice illustrations of amphibians and reptiles.

FIG. 1. Portrait of Georges-Louis Leclerc comte de Buffon (1707–1788) in M. Boitard's *Le Jardin des Plantes. Description et Moeurs des Mammifères* in 1845. Pyenson and Sheets-Pyenson said that "…Buffon added greenhouses and a natural history cabinet" to the garden (p. 154) and that "When the Jardin des Plantes reached its apogee under the old regime, private menageries still flourished in France. Especially important from a scientific standpoint was the comte de Buffon's menagerie at Montbard. There Buffon had purchased the picturesque ruins of an old castle. He reconstructed the castle, planted gardens, established laboratories, and founded a zoological park. He stocked the park with a wide range of exotic animals, which served as a basis for writing his multivolume *Historie naturelle*. At Montbard, he also undertook varied research in experimental zoology, notably in reproduction and hybridization" (p. 168). In *Zoological Illustration*, David Knight says that Buffon "…summed up the work of pre-Linnaean natural historians" (p. 96).

As Director of the Jardin du Roi in Versailles, he became the model of the scientific collector and lobbied for a formalized relationship between the museum and menagerie. He transformed the king's garden into a scientifically significant museum and research center. Buffon became the curator in 1739 and he expanded the gardens greatly. His massive *Histoire naturelle* (36 volumes) [other sources say it was published in 44 volumes between 1749 and 1788, with subscribers purchasing volumes ahead of production. Knight (1977) says that it was 44 volumes, but that the last eight were completed by Lacepède] set out to organize all that was then known about the natural world. Credit: Courtesy of Smithsonian Institution Libraries, Washington, DC.

FIG. 2. Portrait of Baron Georges Cuvier (1769–1832) in M. Boitard's *Le Jardin des Plantes. Description et Moeurs des Mammifères* in 1845. In 1802, he became titular professor at the Jardin des Plantes. His most famous work is the *Règne animal distribué d'après son organisation* (1817; translated into English as *The Animal Kingdom*). Credit: Courtesy of Smithsonian Institution Libraries, Washington, DC.

In 1854–55, Auguste Duméril wrote *Notice historique sur la Ménagerie des Reptiles du Muséum d'histoire naturelle et observations qui y ont été recueillies*, featuring six beautifully hand-colored plus two uncolored plates. This work listed the observations collected at the menagerie, summarized in the Index (Fig. 7). In the *Notice historique*, Duméril included many references to the earlier *Erpétologie générale* so some relevant ones from the *Erpétologie générale* Atlas and one from *Études sur les reptiles* are shown here (Figs. 8–11, 12–20). In three additional papers published by the Museum, Auguste Duméril recorded information about specimens in the Ménagerie. In 1858–61, he provided a list of fishes, reptiles and amphibians, and notes on the menagerie of reptiles. In 1865, reptile and amphibian holdings between 1838–1864 were compiled. New herps in the collection were recorded in the museum archival publication in 1869–70 (Fig. 21).

Arrival of the "Victorian" Building.—The London Zoo opened the World's first reptile building in 1849 (see Murphy, 2007 for details). In 1870–1874, an architect Emile Blanchard designed a reptile menagerie with a pavilion (Figs. 22–24). The facility was 30 m long, with two halls which contained smaller squamates and chelonians. Two large center exhibition halls were called "Crocodile Hall" and "Aquarium Hall;" the latter contained freshwater fishes and amphibians. One unusual feature is that the rear walls of enclosures on the outer wall are glass. As a result, these displays contained living plants which thrived in natural light. The glass-

FIG. 3. Portrait of Bernard-Germain-Etienne de la Ville-sur-Illon comte de Lacepède (1756–1825). This French naturalist, principally known for his herpetological work, published several seminal papers on zoo history, philosophy, and design. Credit: Courtesy of Kraig Adler.

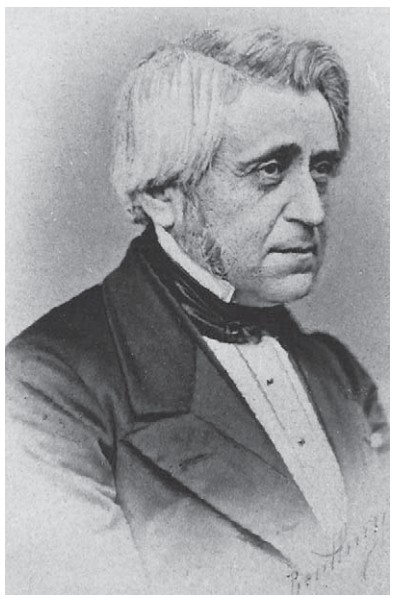
fronted, mahogany cages standing on ornate legs and the marble-walled crocodile pits are still in use (Coote 2001). Bronze sculptures were placed throughout the menagerie: "The Snake Charmer" and "The Crocodile Hunter" by Arthur Bourgeois in front of the reptile pavilion and "Eve" by Guitton near the outdoor crocodile pool.

FIG. 4. Portrait of André Marie Constant Duméril (1774–1860). Credit: Courtesy of Kraig Adler.

In addition to his regular duties in the museum working with the collection, Léon-Louis Vaillant was in charge of the reptile menagerie and aquarium. In 1898, he produced *Muséum d'histoire naturelle guide à la ménagerie des Reptiles*. On the front cover of this guide are drawings of Count de Lacepède, C. Duméril, A. Duméril, and Vaillant himself (Fig. 25). There is a picture of the floorplan (Fig. 26) and another one of visitors enjoying a trip to the reptile building (Fig. 26a).

Scientific Discoveries.—Pierre Bernard mentioned that a female python laid 15 eggs, eight of which hatched in Le Jardin (Bernard 1842–1843). In 1841, Achille Valenciennes reported his observations on the incubating female python (called *Python bivittatus*) at the Menagerie to the French Academy (Valenciennes 1841; Fig. 27). The belief that brooding female pythons produce heat to incubate their eggs was a controversial issue during the nineteenth century (Duméril 1842, 1858). Duméril was convinced that the "cold-blooded nature" of reptiles could not lead to these temperature increases and the issue remained unresolved for many years (see Murphy 2007).

Likely the most famous description presented by Auguste Duméril was his discovery in the menagerie that the larval axolotls of Mexico grow, become sexually mature, reproduce, and yet retain larval features such as external gills—the neotony of *Ambystoma mexicanum* (Figs. 28, 28a). Duméril published papers on reproduction, developmental anomalies, and an amelanotic strain. This now-critically endangered salamander is found in the Xochimilco aquatic ecosystem around Mexico City; this taxon is negatively impacted by pollution threats and invasive species, effects currently under study by a number of zoo biologists (Koenig 2008; Johnson et al., Connect [October 2008:6–9]).



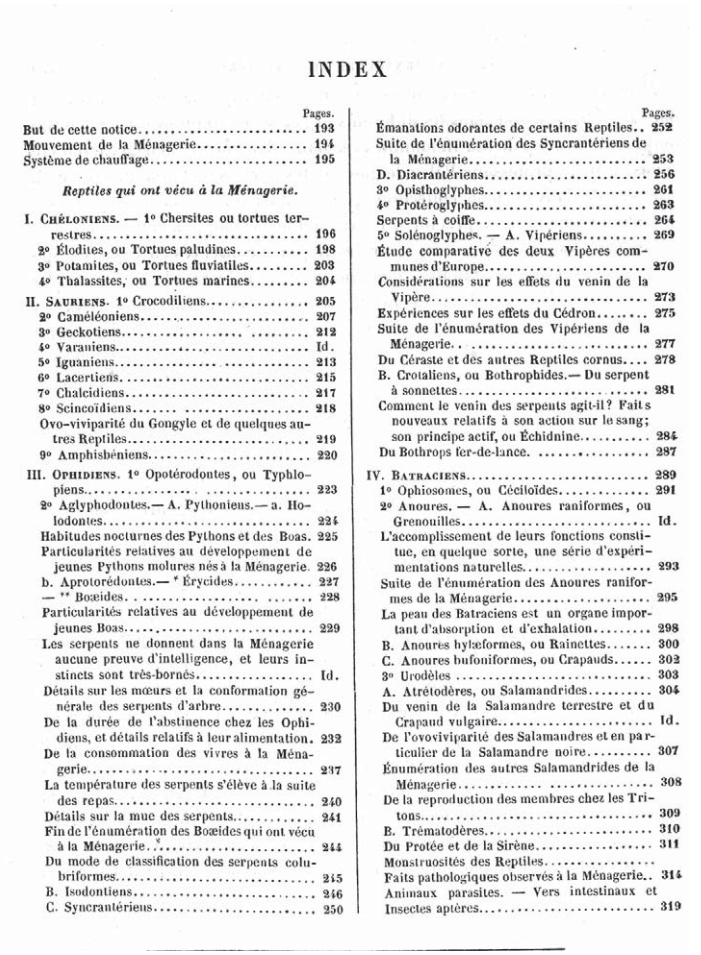


FIG. 5. Portrait of Auguste Henri André Duméril (1812–1870). Credit: Courtesy of Kraig Adler.

Collection.—Deleuze (1823) described an enclosure divided into five parts housing smaller aquatic birds, long-legged birds and gallinaceous fowls, and a large semi-aquatic exhibit for chelonians. The list of species kept was impressive: Radiated, Geometric, Angulated, and Greek Tortoises; Painted, European Pond, Snapping, and Snake-Necked Turtles; Diamondback Terrapin; a number of undescribed taxa; and, amazingly, a Hawksbill Seaturtle which likely lived in fresh water. There were also

Timber Rattlesnakes, African Chameleons, and European Olms on exhibit.

In 1910, the collection numbered 216 reptiles and 237 amphibians. Longevities included a 60-year-old American Alligator, 35 year old Australian turtle, 22-year-old snapping turtle, three giant tortoises over 20 years, Madagascan boa over 21 years, 14-year-old Reticulated Python and a "molure" python two years older, Japanese salamander for 30 years and a siren for 23 years.

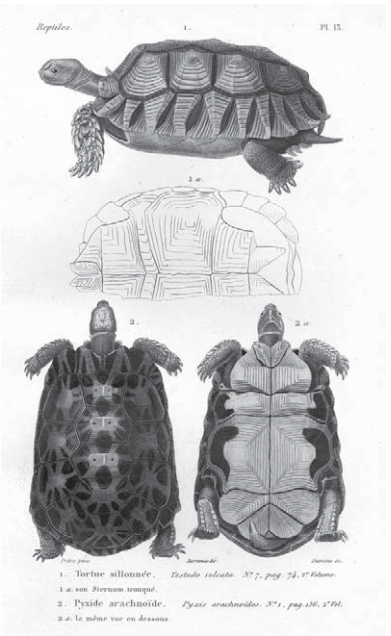

FIG. 8. Illustration of African Spurred Tortoise (*Testudo sulcata*, now *Geochelone sulcata*) above and Common Spider Tortoise (*Pyxis arachnoides*) from *Erpétologie générale*. Credit: Collections of Ernst Mayr Library, Museum of Comparative Zoology, Harvard University.

Jacques Pellegrin at the museum also published on herp longevities at the menagerie: longevity in fish and amphibians (Rev. Gen. Sci. Paris 36:510–512, 1925); longevity in reptiles (Rev. Gen. Sci. Paris 37:47–49, 1926); longevity in alligator (Bull. Mus. Nat. Hist. ser. 2, 9:176–177, 1937). One may consult Flower (1925, 1936, 1937) for additional longevities.

Concluding Remarks.— Count de Lacepède wrote important papers at the museum detailing the mission of zoos, design recommendations, and integration of science. In 1801, he said, "When an animal dies, it is immediately brought to the laboratory of anatomy. There

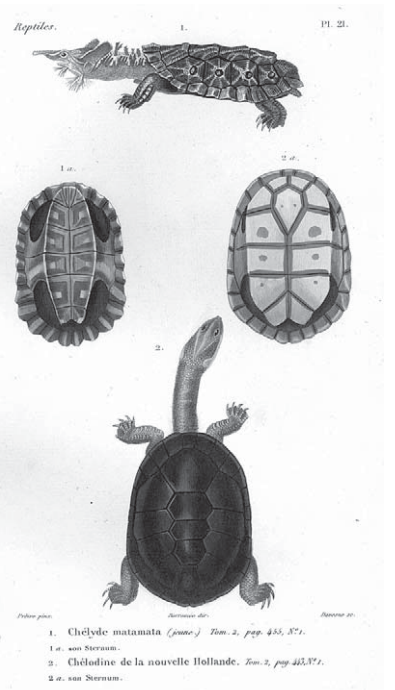

FIG. 9. Illustration of Mata Mata Turtle (*Chelus fimbriatus*) and Snake-Necked Turtle from New Holland from *Erpétologie générale*. The Snake-Necked Turtle called *Chelodina novaehollandiae* is the Common Snake Neck Turtle (*Chelodina longicollis*). Credit: Collections of Ernst Mayr Library, Museum of Comparative Zoology, Harvard University.

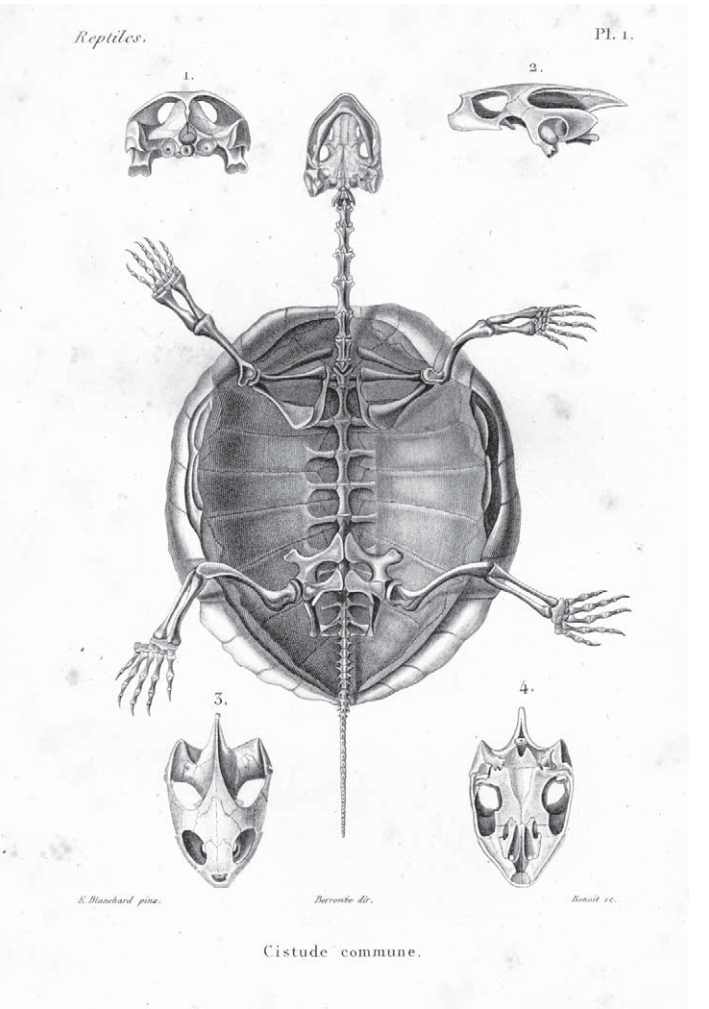

FIG. 10. Illustration of Box Turtle skulls and skeleton from *Erpétologie générale*. Credit: Library of Roy McDiarmid.

the skin is taken and sent to the laboratory of zoology where the professor has it mounted if it is not yet on exhibit." He clearly understood the proper relationship between a museum and a zoological garden, stressing cooperation between the two institutions

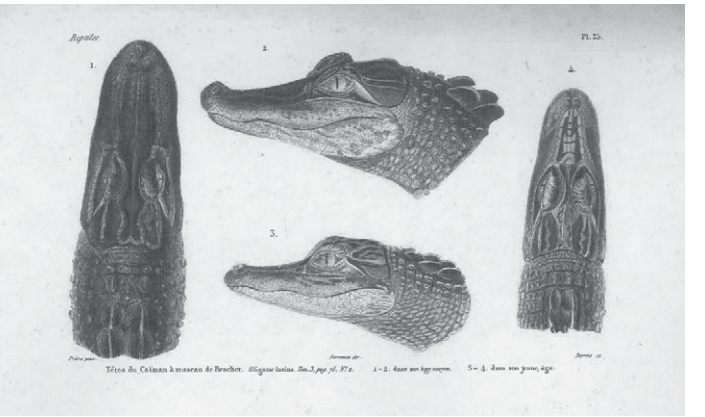

FIG. 11. Illustration of crocodilian heads from *Erpétologie générale*. The scientific name *Alligator lucius* is the old name for the American Alligator. The name "Caiman a Tète de Brochet," is sometimes used in books from the 19th century and is translated as "Caiman with the snout of a pike." Credit: Library of Roy McDiarmid.

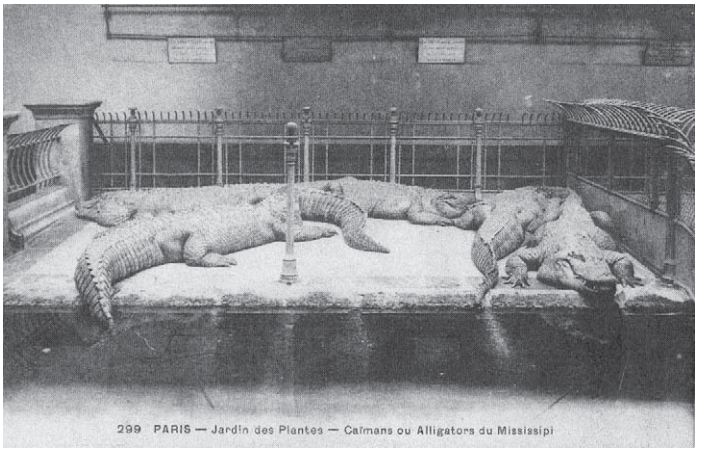

FIG. 11a. In the past, crocodilians were often kept in dense numbers in small enclosures in zoos. In this undated postcard (but possibly from the late 19th or early 20th century), American Alligators are shown in an exhibit at the Jardin surrounded by recurved bars. An American Crocodile was received in 1851 and Émile Wapler from New Orleans donated six American Alligators to the Menagerie the next year where they lived for many years (Duméril, 1854–1855, 1858–1861). Credit: Collection of Smithsonian National Zoological Park.

to use animals upon death to the fullest (see Murphy and Iliff 2004).

There are several examples which serve to illustrate the value of this living collection. Marie Firmin Bocourt learned how to draw herpetological subjects by watching living models at the Ménagerie when he was young. Léon-Louis Vaillant published on reptilian behavior and physiology, based on observations collected at the Ménagerie. Auguste Duméril wrote some of his treatises on the amphibians and reptiles in the Jardin's collection, often accompanied by exquisite illustrations.

The Ménagerie and earlier Terrarium served an important function for artists and biologists from that period—a place where living animals could be observed. As a result, many illustrations published by French biologists began to be more precise: natural poses, fine detail of diagnostic characters, and accurate coloration. Improvements in printing technology

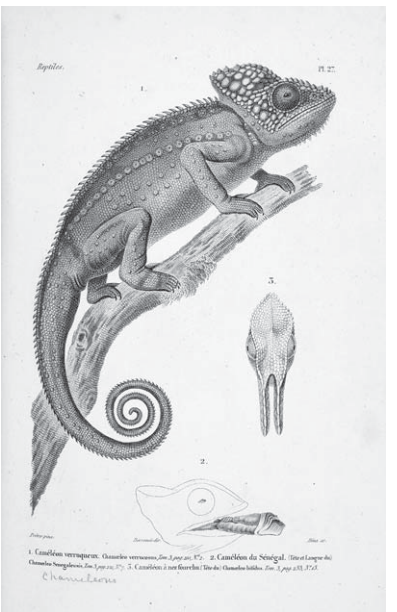

FIG. 12. Illustration of chameleons from *Erpétologie générale*. Auguste Duméril found that European chameleons which began arriving at the Jardin in August 1851 were delicate captives. Over the next four years, more than 160 were kept with none living more than 13 months. His lizards fed on a variety of insects but quickly died. Duméril noticed that females became egg-bound or often died after oviposition and no eggs ever hatched. Credit: Courtesy of Smithsonian Institution Libraries, Washington, DC.

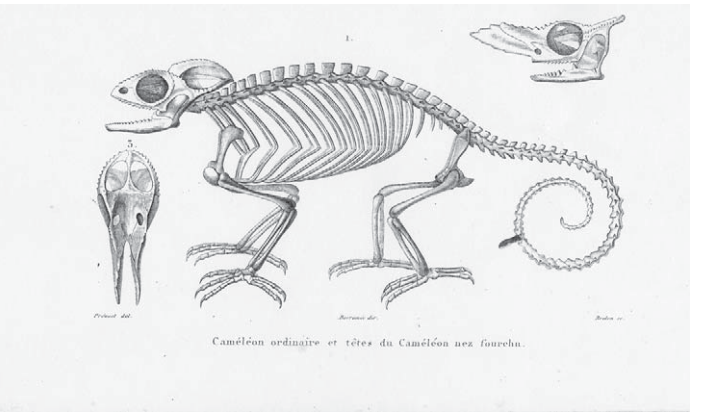

FIG. 13. Illustration of chameleon skulls and skeleton from *Erpétologie générale*. Note that the two outer and three inner fingers are not fused on the forefeet and three outer and two inner toes are not fused on the hind feet. Chaméléon ordinaire is the Common Chameleon (*Chamaeleo chamaeleon*) and the Chaméléon Nez-Fourchu is now *Furcifer bifidis*. Credit: Library of Roy McDiarmid.

also occurred which contributed to this precision. Lithography was important in the late 18th century and multicolored lithographic prints replaced hand coloring in the early 19th century. The improvement in animal illustrations in France and elsewhere in Europe took place in less than 100 years. The change to more realistic depictions of animals came about from the availability of better preserved specimens and live animals, advances in printing technology, and the evolution away from the use of patterns that dominated Renaissance art. This last point is significant, because plant illustration was already very realistic due to the fact that specimens were more widely available (plants were already being pressed and dried and attached to sheets), and the fact that Renaissance animal illustration was still based heavily on myth, as in the bestiary tradition. Consider the contrast between Albrecht Durer's beautiful, lifelike and realistic depictions of a rabbit (an animal he had seen alive frequently) and his famous boiler-plate rhino, an animal he was drawing based on a sketch and description, in the context of the bestiary tradition.

Lavishly illustrated books were designed to be sold not just to people interested in natural history, but those interested in art as well as neither audience was big enough to support the costs

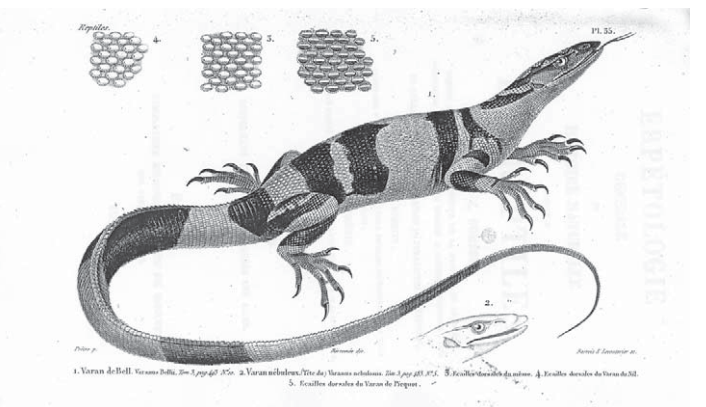

FIG. 14. Illustration of banded phase (sometimes called Bell's Monitor) of the Lace Monitor (*Varanus Bellii*, now V*aranus varius*) and Clouded Monitor (*Varanus nebulosus*) from *Erpétologie générale*. Credit: Library of Roy McDiarmid.

of publication alone (this point is made in Rifkin and Ackerman 2006. *Human Anatomy* [*From the Renaissance to the Digital Age*]. Buffon is a great example of this—his natural history was a very popular book in its day, selling well to the general public as well as naturalists and art collectors. Rifken and Ackerman quote Cuvier as having said that "One must say that without the art of the printer, natural history and anatomy, as they exist today, would not be possible" (p. 271 in their book). More expensive books with hand-colored illustrations sold well to art collectors, then as now.

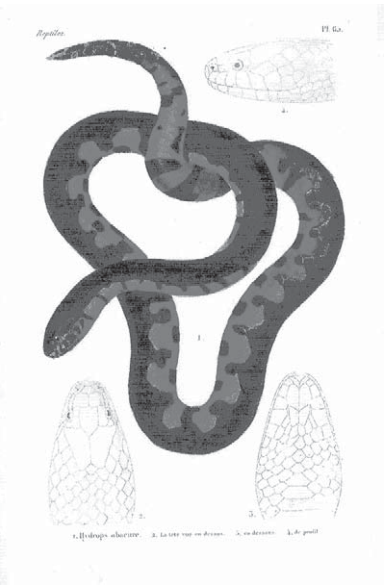

FIG. 15. Illustration of Mud Snake (*Hydrops abacure*, now *Farancia abacura*) from *Erpétologie générale*. Credit: Library of Roy McDiarmid.

Copperplate printing was in use in the mid-16th century, but although copperplates could produce finer lines and hence finer details, the copper plates did not last as long as woodblocks, so woodblocks remained popular with printers for a long time due to their durability. Lithography came out of Germany in the late 18th century, discovered by Alois Senefilder.

I have selected an array of interesting plates which reflect the essence of living herps and the fine artwork created during this period. These will appear in Part II. All colored originals have been converted to a black-and-white format.

Acknowledgments.—This contribution is dedicated to Ken Kawata, retired curator at the Staten Island Zoo in New York. Throughout his professional career, he has stressed the importance of looking at zoo and aquarium history by returning to our earlier roots to improve chances of not duplicating efforts already tried. Kawata has become a mentor to a whole new generation of zoo workers.

I am grateful to Emily Becker, Dana Fisher and James Hanken from the Museum of Comparative Zoology, Harvard University for providing some of the illustrations. Polly Lasker, Smithsonian Institution Libraries, searched archival materials to assure that citations were correct.

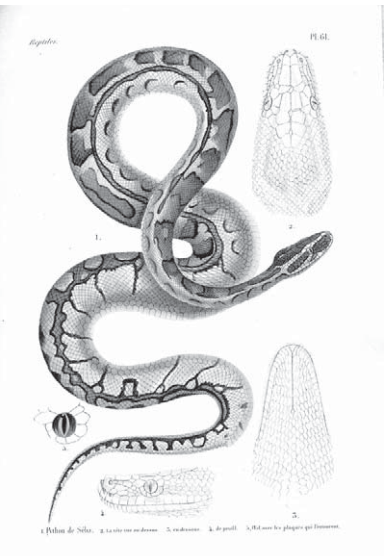

FIG. 16. Illustration of African Rock Python (*Python sebae*) from *Erpétologie générale*. Credit: Library of Roy McDiarmid.

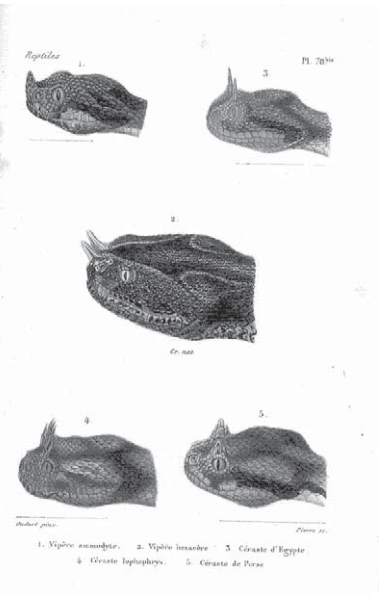

FIG. 17. Illustration of True Viper heads with horns from *Erpétologie générale*. Current common and scientific names are #1 Sand Viper (*Vipera ammodytes*); #2 Rhinoceros Viper (*Bitis nasicornis*); #3 possibly Sahara Sand Viper (*Cerastes vipera*); #4 Many-Horned Adder (*Bitis cornuta*); #5 Persian Horned Viper (*Pseudocerastes persicus*). Credit: Library of Roy McDiarmid.

Thanks are also due to Jean-Luc Berthier, Leslie Overstreet, and Daria Wingreen. My wife Judith Block, Kraig Adler, Jon Coote, Roy McDiarmid, and John Simmons read early drafts and made many helpful suggestions.

FIG. 18. Illustration of snake skulls from *Erpétologie générale*. Current common and scientific names are #1 Reticulate Worm Snake (*Typhlops reticulatus*); #3 Indian Python (*Python molurus*); #4 Emerald Tree Boa (*Corallus caninus*). Credit: Library of Roy McDiarmid.

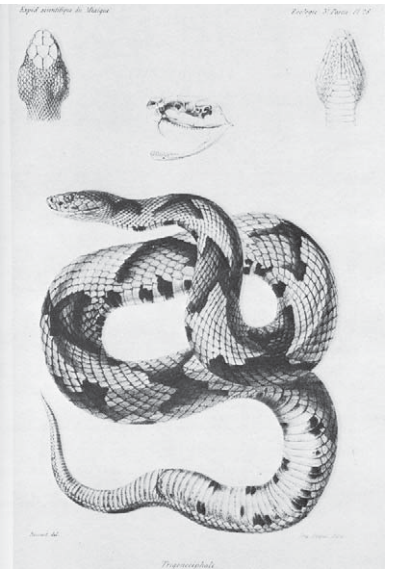

FIG. 19. Drawing of Copperhead (*Trigonocephalus contortrix*, now *Agkistrodon contortrix*) by Firmin Bocourt from *Études sur les reptiles*. Many extralimital species from the United States, South America, and the West Indies were included.

Natural History: The study and description of organisms and natural objects, especially their origins, evolution, and interrelationships.[1]

Definitions of natural history vary, with differences attributable to changing historical perspectives (what we now call "biology" was referred to as natural history until the early 20th century) and motive (either laudatory or derogatory). Recent years have seen a spate of papers addressing the "state" of natural history, whether it's dying or healthy, exactly what encompasses natural history, and what is "good" or "contemporary" natural history. Arnold (2003) and Greene (2005) provided effective, albeit somewhat contradictory, perspectives. Some would suggest that natural history has a long and storied heritage, embodied by great 19th-century naturalists like Alexander von Humboldt and Charles Darwin and their modern-day counterparts like Henry Fitch and John Iverson, whose detailed multi-year studies of the lives of reptiles are primary references for anyone studying those species. In contrast, others propose that natural history today has little relevance beyond a small role in more "conceptual" investigations of our natural world. WordNet (Cognitive Science Laboratory, Princeton University) defines natural history as "the scientific study of plants or animals (more observational than experimental) usually published in popular magazines rather than in academic journals."

Detailed observations of natural history may be deemed old-fashioned and out of vogue—but they will be as valid 100 years from now as on the day they were published. Not surprisingly, Fitch (1987) stated this quite clearly: "When an observer is fortunate enough to see and record behavior significant in the natural history of a species, his observations should be published.... Even a single observation may constitute a valuable contribution and may be a break-through in understanding the species' ecology."

Although we are not particularly interested in entering the debate regarding the state or status of natural history, we do have an interest in the subject—in fact, curiosity regarding the lives of animals in their natural (and often altered) habitats led us to our life-long careers—and, based on our recent experience in accu-

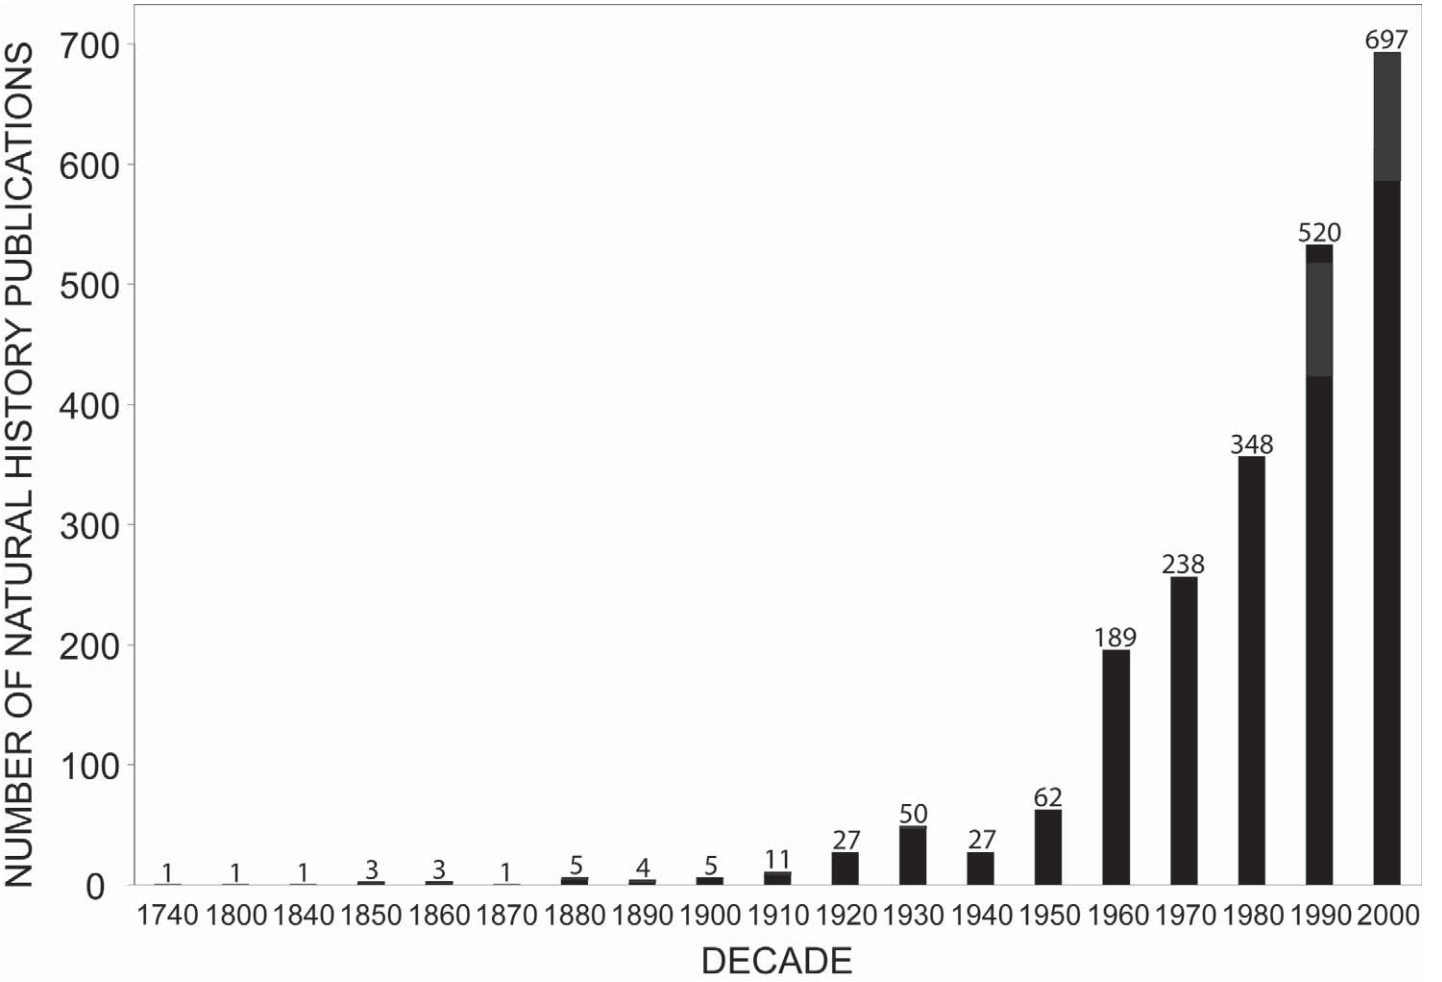

FIG. 1. The number of publications produced by decade (1740–49 ... 2000–09) that include some natural history information relevant to West Indian amphibians and reptiles. The 1910s and 1920s largely represent the efforts of Thomas Barbour (with E. R. Dunn and K. P. Schmidt contributing in the 1920s); Barbour remained active in the 1930s. The drop-off in the 1940s can be attributed to World War II, although Chapman Grant was active at this time. The 1950s mark the initiation of studies by Albert Schwartz and Ernest Williams in the region. Interest in Antillean herpetology blossomed in the 1960s with Orlando Garrido, James Lazell, A. Stanley Rand, Rodolfo Ruibal, Schwartz, Richard Thomas, and Williams as major contributors. By the 1970s, an ecological focus began to share the spotlight with alpha taxonomy through the contributions of Thomas Schoener, Judy Stamps, and others. Research activity has continued to increase in the region to the present day, with major emphases on conservation, ecology, and phylogenetics, with biologists who live on the islands as well as researchers from North America and Europe making valuable contributions. The number of contributions published subsequent to the previous compendium on West Indian herpetology (Schwartz and Henderson 1991) rivals the number published during the previous 250 years.

mulating information for our book on the natural history of West Indian reptiles and amphibians (Henderson and Powell 2009), "natural history" data are being published in a staggering number of journals with an incredibly broad range of foci. Evidently, a great many people remain interested in and are practitioners of natural history.

Background.—In 2005, we proposed to the University Press of Florida a book manuscript summarizing the natural history of each of about 700 species of West Indian frogs and reptiles. We soon thereafter signed a contract agreeing to deliver a 500-page manuscript in December 2007. We both have long histories of working in the West Indies and, we thought, a fairly intimate knowledge of the literature pertaining to its herpetofauna. We were mistaken. By the time we submitted the final version of the manuscript in February 2009 (after reviews and copyediting), it had expanded to over 1800 pages covering 737 species and we had cited more than 2600 sources of information. Those 2600+ citations were gleaned from 317 different sources, including 74 books, 180 book chapters, and more than 300 different scientific journals and publication series. Details of the natural history of Antillean frogs and reptiles came from many obscure (to us) sources, including, for example, the *Journal of Aviation/Aerospace Education and Research*, *Insectes Sociaux*, *Letters in Applied Microbiology*, and *Peptides*. Pertinent literature came from publications originating in nations far removed from the West Indies, including Japan, Russia, and Czechoslovakia. We cited publications that appeared between 1740 and 2009 (Fig. 1), but only 18 publications with some germane natural history data appeared in the 1800s, and another 16 during the first two decades of the 20th century. The numbers began to increase in the 1920s and 30s with the contributions of Thomas Barbour, Emmett R. Dunn, Gladwyn K. Noble, and Karl P. Schmidt. The 1940s showed a decline in relevant publications, almost certainly attributable to WWII. Albert Schwartz and Ernest E. Williams became active in the islands in the 1950s, and this is reflected in the resurgence of activity throughout the Caribbean Region. The 1960s are, we believe, the real turning point for

interest in West Indian herpetology. Schwartz and Richard Thomas, and Williams and his students (most notably A. Stanley Rand) were amazingly prolific, and the number of contributions more than tripled between the 1950s and 60s. The number of contributions containing some natural history information pertinent to the West Indian herpetofauna has steadily increased each decade, with more than 1200 appearing since 1990.

Results.—Henderson and Powell (2009) included 737 species accounts, varying in length from a few lines to many pages. In order to make the accounts as complete and detailed as possible, we sought to include data from all of the relevant sources we could locate, regardless of whether the project from which the published information came was systematic in nature, hypothesis-driven and presented in a conceptual context, or was based on an anecdotal observation. We did not consider the impact factor of journals from which we extracted information. If information was available, no matter how obscure the publication outlet, we felt it was our responsibility to find it (a process that often entailed considerable help from many colleagues throughout the world).

We determined that studies dedicated to some aspect of natural history[2] have addressed 43% of West Indian species. "Dedicated" implies an a priori plan to study some facet of natural history, and that the observations were not based solely on fortuitous occurrences. This by no means suggests that we have a good handle on the natural history of 43% of the Antillean herpetofauna. To the contrary, we have a fairly broad knowledge of only about 5% of West Indian species.

The most frequently cited publication in our book is the *IUCN Red List of Threatened Species* (268 citations; with the vast majority on frogs, reflecting the 2004 Global Amphibian Assessment); the fourth most was the *Catalogue of American Amphibians and Reptiles* (147). Because neither of these generally contains original data, we omit them from our list of the top 10 sources of natural history information pertaining to the West Indian herpetofauna: (1) *Herpetological Review* — 156 citations, (2) *Caribbean Journal of Science* — 151, (3) *Journal of Herpetology* — 107, (4) *Copeia* — 89, (5) *Herpetologica* — 88, (6) *Iguana* (now *Reptiles & Amphibians*) — 69, (7) *Breviora* (Museum of Comparative Zoology) — 53, (8) *Poeyana* (Cuba) — 52, (9–tie) *Ecology* and *Iguana Specialist Group Newsletter* — 31, and (10) *Bulletin of the Museum of Comparative Zoology* — 28.

Most of the top ten was not a surprise. These publications share a willingness (at least historically) to accept and publish studies involving descriptive natural history. *Herpetological Review* (HR) devotes a section to brief natural history observations in each issue, and the *Caribbean Journal of Science* (CJS), based in Puerto Rico, is the most important biological journal published in the West Indies. The *Journal of Herpetology* (JH), although the youngest of the three most influential herpetological journals in North America, provided the most citations, but the number did not differ all that much from those in *Copeia* or *Herpetologica*. *Poeyana* is published in Cuba, and most of its contributions appeared in the 1960s–1980s; today, Cuban herpetologists publish primarily in "mainstream" journals, including HR, CJS, JH, and others in the top ten.

The Museum of Comparative Zoology (MCZ) at Harvard University has a long (>125 years) history of West Indian fieldwork and publications focused on Antillean herpetology. Curators Samuel W. Garman, Thomas Barbour, Ernest E. Williams, and, currently, Jonathon B. Losos have been active in the Caribbean. That the MCZ was the institution that produced the most citations was predictable (87 including six *Memoirs* of the MCZ). Its closest competitor was the American Museum of Natural History with 20. In the West Indies, Cuban herpetologists were far and away the most prolific publishers, often in one of several institution-based publication series.

Based on the *Journal Citation Reports*, the mean impact factor (a measure of the frequency with which the "average article" in a journal has been cited in a given period of time) for the four publications in our top 10 that were listed in the Reports (HR, CJS, *Iguana*, *Breviora*, *Poeyana*, and the *Bulletin of the Museum of Comparative Zoology* were not listed) was 1.620 ± 0.807 (range = 0.527–4.822). By comparison, the average of the top 10 publications (based on impact factor) that we cited, but that did not necessarily make the top 10 of the most frequently cited, was 11.219 ± 2.974 (range = 3.934–28.751). The mean number of times the journals in our top 10 were cited was 82.7 ± 14.7 (range = 31–156), and the mean for the top 10 with the highest impact factors was 9.7 ± 2.8 (range = 2–31). Only one publication (*Ecology*) made both top 10 lists, undoubtedly reflecting the reality that high-impact journals are more likely to include review articles, be interdisciplinary (i.e., not focus on a particular geographic region or taxonomic group), and emphasize topics more "conceptual" than descriptive natural history.

Despite our efforts to be as complete as possible, we are certain that some citations have been missed. Nevertheless, in addition to expanding our own awareness of what we know (and don't know) about many West Indian species, we developed a broader appreciation for the scope of "natural history" and how many aspects of the subject are widely integrated into studies that range far beyond descriptions of how animals make a living in their natural (and sometimes unnatural) habitats.

[2] Our categories of "natural history" included (obviously not all were applicable to all species): abundance, activity, behavior, biomass, burrows (retreats), commensalism, competition, conservation status, defense, desiccation, diet and foraging, disease, distribution, ecomorphology (anoles), ecosystem processes, energetics, growth, habitat, home range, homing, hurricane effects, hybridization, injuries, interspecific (or interclass) interactions, life expectancy, life history, longevity, miscellany, mortality, movement, nesting, parasites, performance, population size and density, population structure, predation, reproduction, salinity tolerance, sex ratios, site fidelity, size, source of introduced populations, survival, swimming, tail autotomy, territoriality, thermal biology, vision, vocalization.

The Little Striped Whiptail (*Aspidoscelis* [*Cnemidophorus*] *inornata*) includes 10 (Wright and Lowe 1993) or 11 (Reeder et al. 2002) subspecies ranging from Arizona, New Mexico, and Texas in the USA, south into Chihuahua, Coahuila, Durango, Nuevo León, San Luis Potosí, and Zacatecas States in México. Although usually faintly to vividly striped dorsally (ornate) over its vast range, individuals and/or populations of inornate (unstriped) *A. inornata* occur at a minimum of one locality in Chihuahua (Cordes and Walker 1996; Walker et al. 1996) and nine in Nuevo León (Axtell 1961; Wright and Lowe 1993; this study). The genetic basis and taxonomic implication of an inornate morph in Nuevo León has been the subject of considerable debate, dating back more than 150 years, with different whiptail investigators drawing conflicting conclusions (Axtell 1961; Baird 1858; Reeder et al. 2002; Wright and Lowe 1993). We discuss taxonomic issues pertaining to *A. inornata* in the context of a widely distributed polytypic species (Liner 2007; Liner and Casas-Andreu 2008; Wright and Lowe 1993) in which there are numerous unresolved problems pertaining to the significance of variation in color pattern (Reeder et al. 2002; Walker et al. 1996; Wright and Lowe 1993). There also exists an alternative classification of populations of "Little Striped Whiptail" in the United States based on the evolutionary species concept. Collins (1997) and Crother (2000, 2008) listed three color-pattern variants (i.e., subspecies sensu Wright and Lowe 1993) from New Mexico and Arizona as species (i.e., *A. arizonae*, *A. gypsi*, and *A. pai*) based on apparent allopatric distributions (Wright and Lowe 1993; p. 134) and morphological diagnosibility. Using these criteria, a minimum of three subspecies recognized by Wright and Lowe (1993) from México also could be elevated to species rank (i.e., *A. cienegae*, *A. chihuahuae*, and *A. paulula*). The genetic contributions of *A. inornata* to the origins of no fewer than two diploid (i.e., *A. innotata* and *A. neomexicana*) and six triploid (i.e., *A. exsanguis*, *A. flagellicauda*, *A. opatae*, *A. sonorae*, *A. uniparens*, and *A. velox*) hybrid-derived parthenogenetic species have been discussed by Densmore et al. (1989a, b) and Wright (1993).

This study pertains to what Baird (1858) described as two species of whiptail lizards from Pesquería Grande (= Villa de García = García), Nuevo León. He named *Cnemidophorus inornatus* to reflect a "...light greenish olive..." dorsum in one, and *C. octolineatus* in allusion to "...eight equidistant and approximated light lines" on the dorsum of the other (Baird 1858; p. 255). Opinions differ on whether *C. octolineatus* should be treated as a synonym of *C. inornatus* (Axtell 1961; Burger 1950; Walker et al. 1996; Williams 1968) or whether these two represent diagnosable taxa (Reeder et al. 2002; Wright and Lowe 1993). That the different color patterns in these otherwise similar forms represent dimorphism within a subspecies is based on Axtell's (1961) report of their coexistence and intimate relationship at a site at Villa de García. The case for partitioning *C. i. inornatus* into two taxa is based on Wright and Lowe's (1993) report of an association of lizards at a different site near Villa de García consisting of inornate and ornate individuals and their possible intergrades or hybrids. Wright and Lowe (1993; p. 136) concluded that "...the possibility that two distinctive taxa (species or subspecies) exist in the vicinity of the type locality is by no means eliminated [by available data]." Most recently, Reeder et al. (2002) placed all species of *Cnemidophorus*, except those in the paraphyletic "*C. lemniscatus*" species group, into the genus *Aspidoscelis*. However, without comment, they allocated inornate lizards from Nuevo León, México, into *Aspidoscelis inornata inornata* (= *Cnemidophorus inornatus* Baird) and revived *A. i. octolineata* (= *C. octolineatus* Baird) from the synonymy of *C. i. inornatus* to accommodate ornate lizards from Coahuila and Nuevo León. Herein, we (1) present data for variation in ornate lizards from Coahuila, (2) data for both ornate and inornate individuals from Nuevo León, (3) list new locality records for inornate lizards from Nuevo León that support recognition of *A. i. octolineata* as a valid taxon, as listed by Reeder et al. (2002), and (4) redefine *A. i. inornata*.

We studied the inornate and inornate specimens of Little Striped Whiptail (*A. inornata*), listed by Axtell (1961) and Wright and Lowe (1993) from the vicinity of Villa de García in the course of a reassessment of their distributional, morphological, and taxonomic relationships. We also examined other samples from Coahuila and Nuevo León for the presence of the inornate form. Specimens were from the following collections (institutional acronyms follow Leviton et al. [1985]): LACM, TCWC, TNHC, UAZ, UCM, USNM (specimens referenced from the literature), UTEP (specimen transferred from another collection), and R. W. Axtell's personal collection (RWA). Each collection site for *A. inornata* was assigned a code consisting of C (= Coahuila) or NL (= Nuevo León) and a number (i.e., C-1–C-24 and NL-1–NL-17; Appendix 1). Two type specimens (USNM 3032A [lectotype] and 3032B [paralectotype]; Baird 1858; Wright and Lowe 1993) from the type locality, six lizards from NL-1 (Axtell 1961), and nine from NL-2 (Wright and Lowe 1993) have previously served as vouchers for inornate *A. inornata* from Nuevo León. We studied 42 additional inornate specimens from the state, which were held in LACM, RWA, and TCWC. These specimens were from NL-2

(10 inornate [IN] and 48 ornate [OR] lizards), northwest of the type locality (four IN and one OR at NL-3 and one IN and no OR at NL-4), and sites accessed by the part of México Highway 53 extending northwest from Mina to the Nuevo León–Coahuila border (27 IN and no OR at NL-5–9). We used Google Earth (www.earth.google.com) to locate collection sites with known coordinates, scan topography, determine elevations, and measure line distances between sites from which *A. i. inornata* has been collected in Nuevo León. However, the exact spatial relationship of the sites originally visited by RWA (NL-1) and by J. W. Wright and associates (NL-2) could not be determined as no coordinates were included in the catalog entries for Wright's UAZ and LACM samples. We used the Federal Communications Commission website (www.fcc.gov/mb/audio/bickel/DDDMMSS-decimal.html) to convert data accompanying museum samples for degrees, minutes, and seconds to decimal degrees latitude and longitude.

Meristic characters (terminology after Burt 1931; Smith 1946; Walker et al. 1996; Wright and Lowe 1993; Tables 1, 2) included counts of: (1) granules (= scales) at midbody from the right outer row of ventral scales over the body to the left outer row of ventral scales (GAB), (2) dorsal granules longitudinally from the occipitals to the first row of caudals (OR), (3) granules between the paravertebral stripes at midbody (PV; only possible for ornate lizards), (4) percent of granules around midbody between paravertebral stripes (PV/GAB x 100; only possible for ornate lizards), (5) femoral pores (FP, summed from both sides), (6) subdigital lamellae of the fourth toe of the left pes (SDL), (7) circumorbitals (COS; summed from both sides), (8) lateral supraocular granules (LSG; summed from both sides), and (9) interlabials (ILS; summed from both sides). Each specimen of *A. inornata* was sexed (via inspection of femoral pores and cloacal region), and its snout–vent length (SVL) measured to the nearest mm (Table 1).

We used ANOVA in JMP v. 7 (SAS Institute, Cary, NC) to generate a mean ± 1 SE for SVL pooled by sex, and for each univariate character of scutellation in each geographical and pooled sample of *A. inornata* (Tables 1, 2). We selected the treatment "All Pairs-Tukey-Kramer HSD" to determine statistical differences between any two means. This procedure yields post-hoc comparisons, which preserves alpha ($P < 0.05$) in statistical comparisons of multiple means (Sokal and Rohlf 1981). Chi-square values were computed using SPSS v. 14.1 (SPSS, Chicago, IL) to separately compare ratios of numbers of dorsal color pattern variants designated A–D for the 1962 UAZ and 1975 LACM samples of *A. inornata* from site NL-2 in Nuevo León.

Aspidoscelis i. inornata lacks dorsal stripes and spots (Fig. 1A, B, C). In contrast, *A. i. octolineata* has 7–11 pale longitudinal dorsal stripes and darker intervening fields; each side of the body (ventral to dorsal) has a lateral, a dorsolateral, and a paravertebral primary stripe (Fig. 1D, J, L). The middorsal region between the paravertebral stripes in each ornate lizard has 1–4 additional supernumerary stripes (sensu Wright and Lowe [1993], if more than the usual number of two). We used "7+ stripes" to denote the presence of an intermittently joined and split vertebral stripe between the head and tail of a lizard. In ornate *A. inornata*, the dark fields between the stripes always lack spots; however, certain fields may develop an indistinct longitudinal line (supernumerary stripes, sensu Walker et al. [1996]) between the primary stripes.

Axtell (1961) described an area ca. 50 × 100 m of wind-formed sand mounds just under 3 m high at NL-1, referenced by him as the type locality of *A. inornata*, from which he collected six inornate and five ornate specimens (three ornate lizards were obtained approximately 100 m to the southeast among mounds less that 0.5 m high). He described each of the inornate adults from NL-1 as having a "...completely unicolor brownish olive..." dorsum and each of the ornate adults as being "...distinctly striped with eight light lines on a brownish gray to olive background..." (Axtell 1961; p. 149). None of these specimens was intermediate in color pattern between the inornate and ornate morphotypes. A return to NL-1 by RWA in the 1960s revealed that the area previously inhabited by inornate and ornate *A. inornata* had been destroyed by construction activities.

Wright and Lowe (1993) described a differently constituted association of whiptail lizards at site NL-2 located 1.6 km west and 1.6 km south of Villa de García, where inornate and ornate *A. inornata* and apparent intergrades (or hybrids) were collected. We agree that adults UAZ 14067–75 are inornate (our variant A; 29.0%) and that adults UAZ 14076–88, 14093–95, 14097–102 are ornate (our variants B–D; 71.0%), the latter having stripes ranging from distinct to indistinct, straight to irregular, and with or without supernumerary stripes. Among the inornate specimens are four females (UAZ 14067, 14069, 14072, 14075; 54–60 mm SVL) and five males (UAZ 14068, 14070–71, 14073–74; 55–60 mm SVL). Among the 22 ornate specimens in the UAZ sample are four females (UAZ 14078, 14080, 14083, 14095; 57–61 mm SVL) and one male (UAZ 14099; 60 mm SVL) (designated variant B; 22.7%) with gray-tan fields of only slightly darker hues than the stripes; four of these individuals have 9–10 stripes rather than the usual number of eight, and in some the stripes are atypical. In the ornate group from NL-2 designated variant D (50%), six females (UAZ 14077, 14079, 14082 [Wright and Lowe (1993, figure 7)], 14093, 14097–98; 58–62 mm SVL) and five males (UAZ 14081, 14085, 14087 [Wright and Lowe (1993, figure 7)], 14094, 14101; 56–60 mm SVL) have the pattern of *A. i. octolineata* comparable to specimens from NL-12, in which dark fields strongly contrast with seven (one specimen), eight, or nine pale stripes. Last, in the ornate group from NL-2 designated variant C (27.3%) are three females (UAZ 14076, 14086, 14088; 56–58 mm SVL) and three males (UAZ 14084, 14100, 14102; 58–61 mm SVL) with dorsal patterns of intermediate contrast between the fields and stripes.

A large unreported sample of *A. inornata* collected in LACM from NL-2 in 1975 includes seven (14.0%; LACM 116195–201; Fig. 1A, B, C) inornate and 43 (86.0%; LACM 116152–94) ornate specimens of *A. inornata*. Among the ornate lizards are six (14.0%, Fig. 1D, E, F) of variant B, nine (20.9%, Fig. 1G, H, I) of variant C, and 28 (65.1%, Fig. 1J, K, L) of variant D. Another unreported LACM sample from NL-2 collected in 1980 includes three (37.5%) inornate and five (62.5%) ornate specimens of *A. inornata*.

The variation in color pattern described above in samples from NL-1 and NL-2 is not attributable to either sexual dimorphism or ontogenetic development; both males and females over a similar SVL range in both groups have the patterns described. We concur with Wright and Lowe (1993) that some of the variation observed among the ornate specimens from NL-2 likely reflects gene exchange between inornate and ornate lizards. The disparate ratios of inornate to ornate lizards in the 1962 (9:31, $\chi^2 = 5.452$, $P = 0.02$) and 1975 (7:44, $\chi^2 = 26.843$, $P = 0.0005$) samples from NL-2 are

TABLE 1. Meristic characters (see text for definitions of abbreviations) of *Aspidoscelis inornata* from Nuevo León, México. Data are (first row) mean ± SE, (second row) range and (N) and tabulated by site code (see text for explanation), color pattern variant (IN = inornate *A. i. inornata*), OR = ornate *A. i. octolineata*), and museum collection.

not likely explained by chance or sampling effort. The 1975 sample also includes fewer ornate individuals with unusual stripe characteristics than were present in the 1962 sample. Although the 1962 sample has statistically indistinguishable frequencies of the three ornate variants represented in Fig. 1 ($\chi^2 = 2.818$, $P = 0.24$), this was not the case for the 1975 sample ($\chi^2 = 21.318$, $P = 0.0005$).

In Nuevo León, inornate lizards were previously known from two sites at Villa de García, both also inhabited by ornate lizards (Axtell 1961; Wright and Lowe 1993) and one with intergrades or hybrids of the two (Wright and Lowe 1993). We describe a distribution area for the inornate variant in Nuevo León of larger size than those of subspecies of Little Striped Whiptail in México (e.g., *A. i. cienegae*) and the United States (e.g., *A. i. gypsi*) (Wright and Lowe 1993, p. 134). This area in Nuevo León extends from Villa de García and La Paz thence north–northwest to southeast of Soledad (spanning 25.8167–26.3333ºN latitude, 100.5833–100.8333ºW longitude, and 693–930 m elevation). The linear distance between the most widely separated sites for inornate lizards (i.e., *A. i. inornata*) in Nuevo León is ca. 65 km from NL-2 to NL-9.

In addition to the two sites noted, both inornate (TCWC 44262–65) and ornate (TCWC 44261) individuals of *A. inornata* also occur at a third site (NL-3), located 14.1 km NW of Villa de García, Nuevo León. Two juvenile males from NL-3 (TCWC 44263 and 44264) are the smallest (36 and 39 mm SVL, respectively) inornate lizards known to us. In ethanol, both are similar to adults in that they lack stripes and have a gray-brown dorsum. One male (TCWC 44266) from NL-4 at 1.6 km west of La Paz establishes the presence of the inornate variant at a fourth site in the general area of Villa de García. All other samples of inornate lizards were collected well north of Villa de García, the largest sample consisting of 13 adult males (TCWC 43591–92, 43595–98, 43600–01, 43603–04, 43606, 43610–11; 54–59 mm SVL) and eight adult females (TCWC 43593–94, 43599, 43602, 43605, 43607–09; 51–64 mm SVL) from NL-5 at 8.2 km west of Mina. Specimens of *A. marmorata* with strongly contrasting dorsal patterns also occur at NL-5 and nearby (Hendricks and Dixon 1986). Only inornate specimens of *A. inornata* are present in samples from NL-6 (N = 1), NL-7 (N = 1), NL-8 (N = 3), and NL-9 (N = 1), which are between 8.2 km northwest of Mina and 17.8 km southeast of Soledad over a road distance of about 42 km. Two samples containing ornate lizards from 0.6 km southeast of Soledad (NL-10, N = 1) and 4.0 km northwest of Soledad (NL-11, N = 6) suggest that *A. i. octolineata* replaces *A. i. inornata* to the northwest of NL-9. All 143 specimens of *A. i. octolineata* that we examined from 24 sites in southwestern Coahuila (Appendix 1) have ornate patterns consisting of 7+ (27.2%), 8 (38.1%), or 9 (34.5%) stripes.

No statistical differences were found between the pooled mean SVL for each of inornate females, inornate males, ornate females, and ornate males of our sample of 189 adult *A. inornata* from Coahuila and Nuevo León (Table 2). Likewise, we found no significant differences in scutellation (excluding PV and PV/GAB) between samples of inornate lizards collected at NL-2 in 1962 versus those from 1975 and 1980, between samples of ornate lizards collected at NL-2 in 1962 versus those from 1975 and 1980, or between all

samples of inornate and ornate individuals from NL-2 (Table 2). We suspect that the greater variation in GAB, OR, FP, COS, LSG, and ILS in ornate relative to inornate lizards from NL-2 is a reflection of the larger sample size of ornate lizards (N = 65 vs. 15, respectively). Sample sizes were sufficient (N ≥ 4) to compare scutellation data of inornate lizards from Nuevo León for only three sites: NL-2 (N = 15), NL-3 (N = 4), and NL-5 (N = 21). The only significant difference among these samples for the seven characters we studied was the number of FP between NL-2 (34.0 ± 0.51) and NL-5 (36.9 ± 0.56). Among the ornate lizards from Nuevo León, sample sizes were sufficient (N ≥ 6) to compare scutellation data for three sites as well: NL-2 (N = 65), NL-11 (N = 6), and NL-12 (N = 8). The only significant difference for nine characters in these samples (Table 1) was SDL between NL-2 (29.6 ± 0.20) and NL-12 (32.3 ± 0.49). We pooled all inornate and ornate individuals of *A. i. inornata* from Nuevo León into separate samples for comparisons of univarate meristic characters (Table 2). Significant differences were found between two characters in the pooled samples: OR (179.0 ± 1.26 for inornate and 182.6 ± 1.13 for ornate lizards) and FP (35.8 ± 0.37 for inornate and 34.8 ± 0.32 for ornate lizards). Examples of significant differences between Nuevo León and Coahuila samples of *A. i. inornata* are apparent in OR and PV (Table 2).

TABLE 2. Summary of meristic characters and SVL (see text for definitions of abbreviations) for *Aspidoscelis inornata inornata* (inornate) from Nuevo León and *A. i. octolineata* (ornate) from Nuevo León and Coahuila, México. Data are mean ± SE (first row) and range and (N) (second row).

Character	Nuevo León *A. i. inornata*	Nuevo León *A. i. octolineata*	Coahuila *A. i. octolineata*
GAB	70.5 ± 0.48 64–80 (44)	71.0 ± 0.38 64–81 (80)	68.7 ± 0.66 57–79 (59)
OR	179.0 ± 1.26 160–191 (44)	182.6 ± 1.13 154–205 (80)	172.4 ± 1.63 140–178 (59)
PV	— —	16.5 ± 0.30 13–21 (81)	14.5 ± 0.33 7–21 (59)
PV/GAB	— —	23.3 ± 0.30 17.8–30.4 (80)	21.0 ± 0.40 10.3–26.5 (59)
FP	35.8 ± 0.37 31–44 (44)	34.7 ± 0.28 32–40 (81)	34.8 ± 0.32 30–41 (59)

SVL (males)	56.8 ± 0.46 51–62 (28)	57.4 ± 0.39 51–63 (45)	56.1 ± 0.55 52–65 (37)

Specimens of *A. inornata* referenced in this study voucher new distribution records extending the known range of this species in western Nuevo León well north of Villa de García. Several samples from northwest of Mina, which include only inornate lizards, indicate that true-breeding demes occur in the absence of ornate lizards in a sizeable area of northwestern Nuevo León. Consequently, we agree with Reeder et al. (2002) that the striped subspecies from Coahuila and several sites in Nuevo León, which was previously known as *A. i. inornata*, should be recognized as *A. i. octolineata*, and that the inornate form in Nuevo León be recognized as *A. i. inornata*. Moreover, our analyses of samples of *A. inornata* from UAZ and LACM collected in 1962 and 1975 revealed that the relative abundance of the inornate and ornate B–D variants at NL-2 might vary over time, possibly as a result of fluctuations in rates of gene flow among co-occurring populations of the color-pattern variants. The extent of geographic coexistence between inornate and ornate pattern types in the general vicinity of Villa de García appears to be on the order of a few hectares.

Elsewhere within the range of Little Striped Whiptail, there are either populations or individual lizards with dorsal patterns that trend toward the extreme inornate morph. Wright and Lowe (1993) described *A. i. gypsi* from the White Sands Missile Range (WSMR) in the Tularosa Basin, Otero County, New Mexico, based on a dorsal pattern of reduced contrast between stripes and fields. However, Rosenblum (2005, 2006) and Rosenblum et al. (2004) have intensively investigated the evolutionary and ecological implications of this blanched dorsum in *A. inornata*, but did not draw taxonomic conclusions. Persistence of this color combination on matching sand dune formations is an apparent result of selection for crypsis (Dixon 1967; Rosenblum 2005, 2006; Rosenblum et al. 2004), and may be an apomorphy of the pale stripes and dark fields in *A. i. llanuras* in areas peripheral to WSMR. We infer that complete loss of stripes in *A. i. gypsi* by gradualism is unlikely, as that would require loss of the genetic potential for organization of dorsal pigment into a lineate (i.e., ornate) pattern.

That an unstriped pattern can arise spontaneously in a population of *A. inornata* is shown by the discovery of such individuals at Picacho, west of the Río Conchos, Chihuahua. At Picacho, well within the range of *A. i. heptagramma*, there is a population of ornate lizards characterized by unusual striping among which inornate individuals are occasionally found (Cordes and Walker 1996; Walker et al. 1996, figure 2). Repeated visits to this site by JEC in different years produced no evidence that the proportion of inornate individuals is increasing in the population. Although the genetic basis of color expression in *A. inornata* is inadequately known despite intensive research on *A. i. gypsi* by Rosenblum et al. (2004), we suspect that the inornate pattern of *A. i. inornata*

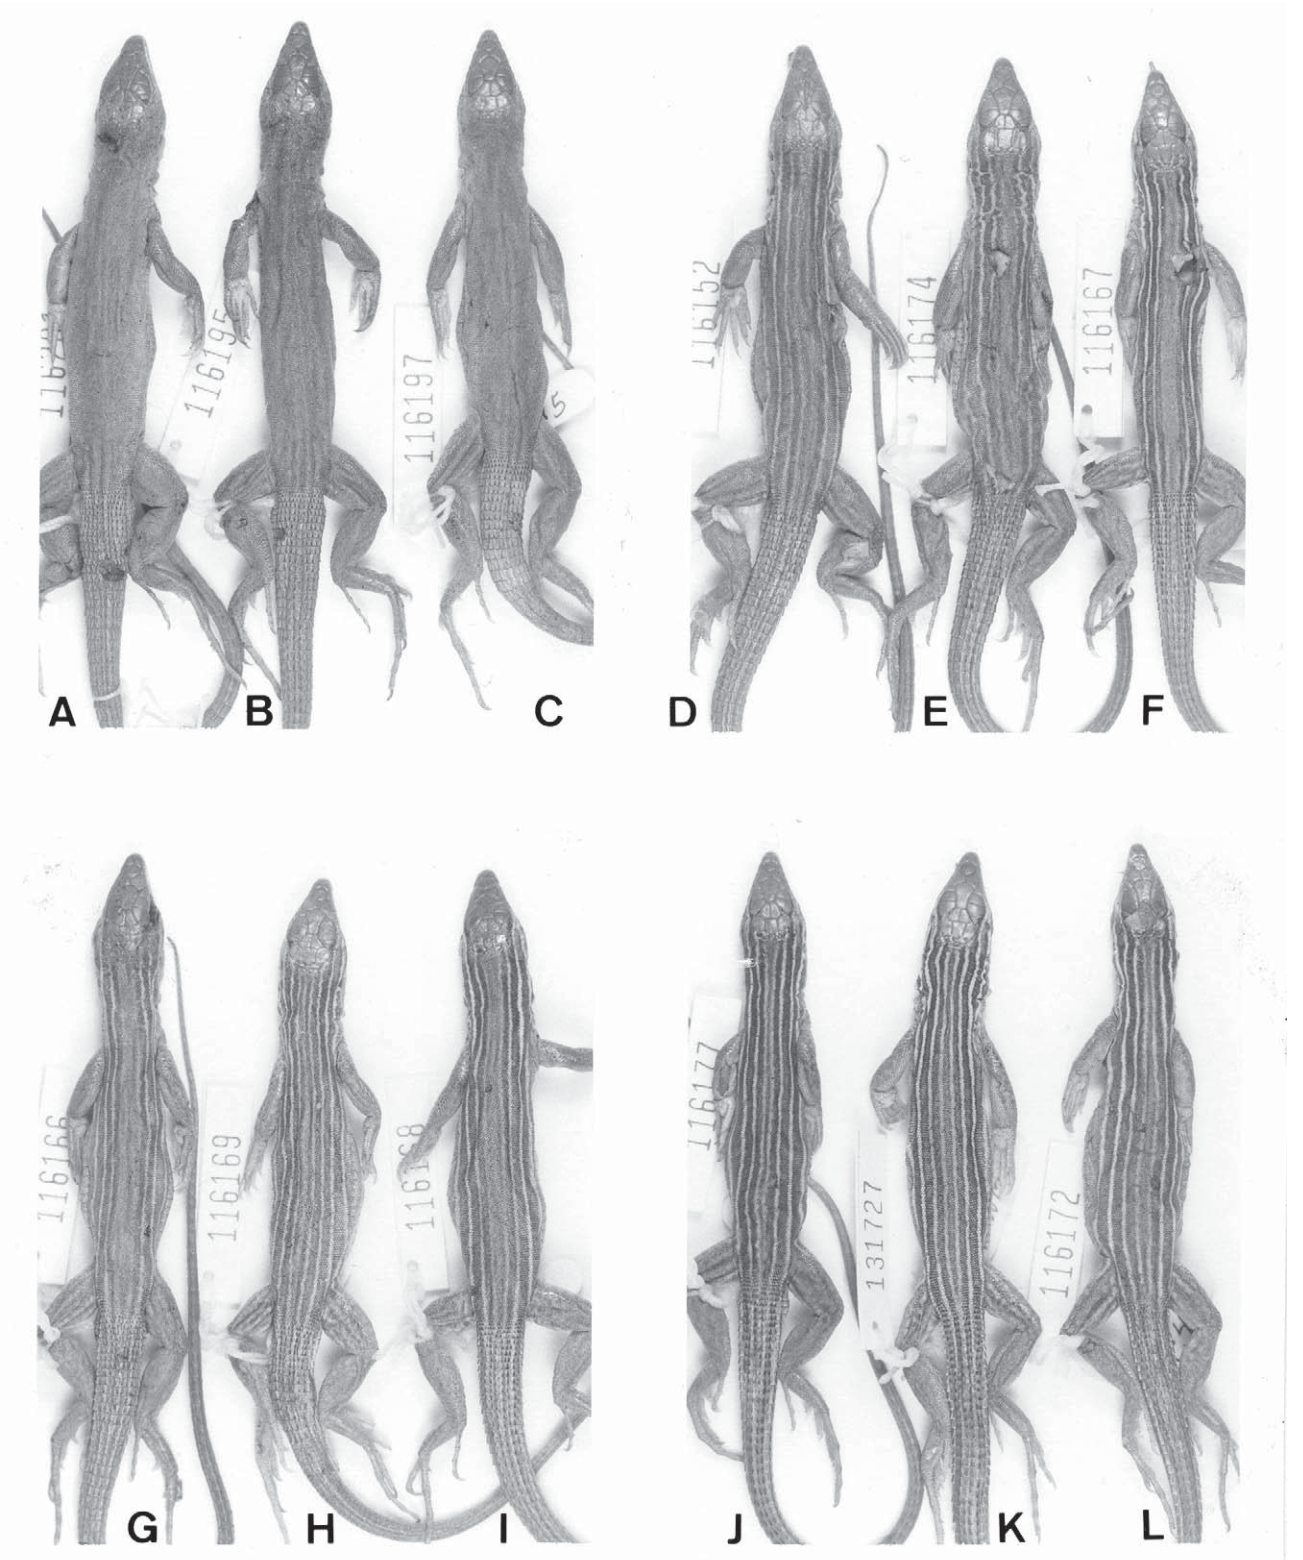

FIG. 1. Dorsal color-pattern variation in *Aspidoscelis inornata* from 1.6 km W, 1.6 km S of Villa de García (NL-2), Nuevo León, México in LACM collection (A, LACM 116201, 60 mm SVL; B, LACM 116195, 62 mm SVL; C, LACM 116197, 56 mm SVL; D, LACM 116152, 60 mm SVL; E, LACM 116174, 57 mm SVL; F, LACM 116167, 55 mm SVL; G, LACM 116166, 60 mm SVL; H, LACM 116169, 58 mm SVL; I, LACM 116168, 61 mm SVL; J, LACM 116177, 57 mm SVL; K, LACM 131727, 61 mm SVL; L, LACM 116172, 60 mm SVL). A–G, J are males; H–I, K–L are females.

in Nuevo León appeared suddenly as was reported for specimens with unstriped dorsal pattern at Picacho, Chihuahua (Walker and Cordes 1996). In fact, *A. i. inornata* is the only taxon in the diverse *A. sexlineata* species group characterized by absence of stripes at all ontogenetic stages of pattern development. We infer that this attribute in *A. i. inornata* represents one or more mutations

that have silenced the mechanism involved in the organization of pale dorsal stripes, as was deduced for the few individuals from Picacho, Chihuahua. Although contact zones for *A. i. inornata* and *A. i. octolineata* at Villa de García have been known from as early as the 1850s (Baird 1858) until as late as the 1980s (this study), elsewhere in Nuevo León the inornate subspecies has either replaced the ornate subspecies or now inhabits areas where it does not occur.

Acknowledgments.—We are grateful to the following curators and collection managers for the opportunity to examine specimens of *A. inornata* in their care: G. Bradley (UAZ), K. Vaughan (TCWC), D. Cannatella and J. Rosales (TNHC), D. Kizirian and K. Beaman (LACM), and A. de Queiroz and R. Humphrey (UCM). Ernest Liner provided information about his experiences with *A. inornata* in Nuevo León, J. Wright provided helpful information, and H. Taylor provided advice on statistical procedures. Special appreciation is extended to E. Rosenblum for critically reading a version of the manuscript, without specific endorsements of any part of it. Constructive criticism by reviewers T. Reeder and C. J. Cole, and associate editor R. Espinoza, were indispensable in sharpening the focus of the paper.

Amphibian declines are taking place worldwide, but are most prevalent among montane stream-associated species in the neotropics (Stuart et al. 2004). Some of these declines are due to habitat loss, but many are taking place in seemingly pristine habitats (Stuart et al. 2004). Lips et al. (2006) reported the link between the chytrid fungus *Batrachochytrium dendrobatidis* and a rapid mass mortality and loss of amphibian diversity at a site in Panama. Pounds et al. (2006) provided evidence that the chytrid fungus in combination with global warming may be responsible for the disappearances of various species of the neotropical frog genus *Atelopus*.

The Honduran endemic montane streamside frog *Craugastor milesi* (Schmidt) was last seen alive in 1983, even though one of its known localities remains in a pristine condition (McCranie and Castañeda 2007; McCranie and Wilson 2002). Subsequently, numerous efforts to find this frog at its remaining pristine locality in Parque Nacional Cusuco have failed (McCranie and Castañeda 2007; McCranie and Wilson 2002; Townsend and Wilson 2008), even though it was a common frog at that locality in the late

FIG. 1. Adult male *Craugastor milesi* found 29 June 2008 in Parque Nacional Cusuco, Honduras.

1970s and early 1980s. Consequently, *C. milesi* was one of only nine New World anuran species classified as extinct by Young et al. (2004).

On 29 June 2008, an adult male *Craugastor milesi* (Fig. 1) was collected in Parque Nacional Cusuco while conducting a nocturnal herpetological survey. The site was located at an elevation of 1841 m and the weather was cool and breezy with light precipitation. A nearby data logger recorded the air temperature to be 16°C during this period of activity. The specimen was perched on a low branch along the edge of a small montane stream. This stream is a tributary of the larger Rio Cantilles, with which it joins approximately100 m downstream from the collection site. A skin swab was collected from this specimen for the detection of *B. dendrobatidis*. The sample was processed by PCR analysis and produced a negative result for infection.

On 30 June 2008 and 5–6 July 2008, extensive day and nighttime surveys of the same site and surrounding habitat failed to produce additional specimens of *Craugastor milesi*. During these surveys, four *Plectrohyla dasypus* larvae were collected from the stream and swabbed for *B. dendrobatidis*. Two of the four tadpoles exhibited severe oral defects and subsequently tested positive for infection. Surveys along portions of the nearby Rio Cantilles were similarly unsuccessful in locating additional *C. milesi*, but revealed the presence of *B. dendrobatidis* in six out of seven additional *P. dasypus* larvae. Although other *Craugastor* species could be found widely distributed across Parque Nacional Cusuco, the forest surrounding the *C. milesi* collection site appeared to be unusually devoid of terrestrial anurans.

The rediscovery of *Craugastor milesi* in Parque Nacional Cusuco is significant in light of the current global amphibian extinction crisis. Despite the common global threat of habitat destruction, the pristine condition of Parque Nacional Cusuco during the 1980s negates habitat destruction as a possible explanation for the unexpected disappearance of *C. milesi*. The most likely agent responsible for *C. milesi*'s demise, *B. dendrobatidis*, has recently

been identified in Parque Nacional Cusuco and may be responsible for the declining populations of several other critically endangered amphibian species in the park (Kolby et al. 2009). If true, the discovery of an uninfected adult *C. milesi* from within the heart of a *B. dendrobatidis*-ridden habitat produces hopeful implications for resistance to chytridiomycosis, as it is highly unlikely that this individual successfully evaded infection throughout development while being exposed to contaminated water sources.

On 14 July 2007, a specimen with striking resemblances to *C. milesi* was encountered in direct proximity to the confirmed collection site in 2008, but efforts to capture and positively identify this specimen proved unsuccessful at the time. Although a genetically robust population of *C. milesi* may exist in Parque Nacional Cusuco, it is too early to estimate the extant population size and determine whether this species is rebounding from the brink of extinction or still in a period of decline.

Acknowledgments.—Financial support was provided by the National Geographic Society (Young Explorers Grant C146-08), and Omaha's Henry Doorly Zoo. Collection and export permits were granted by C. Cárcamo de Martínez of AFE-CODEHFOR, Tegucigalpa. K. Hunter conducted the PCR analysis for *B. dendrobatidis*. Personnel of Operation Wallacea provided crucial logistical support while in the field.

São Luís- MA, Brazil

Brazil has an extensive coastline in the state of Maranhão, including many islands and a continental area called the "Baixada Maranhense," where several turtle species of the families Chelidae, Pelomedusidae, Kinosternidae, and Emydidae occur. Both *Kinosternon scorpioides* and *Trachemys adiutrix* occur on Curupu Island. *Kinosternon scorpioides* lives in both still and running water, frequently in areas affected by human activity, especially drainage canals (Pritchard and Trebbau 1984). This species is distributed from Mexico to South America, where it thrives along the coast in Colombia, Guiana, Trinidad, and Brazil as well as the interior of the Amazon to Bolivia (Pritchard and Trebbau 1984). The genus *Trachemys* ranges from North America into Central America (Savage 1966), southern Brazil, Uruguay, and Argentina (Vanzolini 1995) and has the largest geographic distribution of any turtle genus in the New World (Seidel 2002). *Trachemys adiutrix* is an aquatic species that inhabits permanent and seasonal bodies of water, and may move great distances during the rainy season (Vanzolini 1995). The only published reference on *Trachemys* in Maranhão is the original description of *T. adiutrix* from the northeastern region of the state (Vanzolini 1995). Information on the occurrence of *K. scorpioides* in the coastal region of Brazil consists of one record reported by Pritchard and Trebbau (1984), who observed the species on Marajó Island, Pará state. Because little is known of *K. scorpioides* and *T. adiutrix*, we report data on selected aspects of their biology in the coastal zone of northeastern Brazil. We specifically examined reproductive ecology (nesting behavior and season) and population structure of these two species.

Materials and Methods

Curupu Island (2.4025°S, 44.0219°W) is located ca. 30 km from the center of São Luís, state of Maranhão, Brazil. The island is ringed by extensive sandy beaches, with flooded fields, marshy vegetation, dunes, freshwater lagoons, and mangroves further inland. The rainy season extends from January to June and the dry season from July to December. Two-day sampling periods were conducted every 15 d throughout the year from August 2000 to March 2002 (Figs. 1, 2). During each sampling period, data were

collected between 0500 h and 1200 h. During each field visit, we captured turtles in three lagoons located in the central part of the island. These lagoons were located ca. 20 m apart and were ca. 400 m^2 in area each. They ranged from oligotrophic to eutrophic and contained an abundance of macrophytes, pteridophytes, macroalgae, and fish. Turtles were collected using baited funnel traps (one trap per lagoon) constructed of wooden slats with a funnel entrance. These traps were made by the local community using wood stems or wire, and were similar to crayfish traps (Rocha et al. 1997). Traps were baited with fresh fish and placed in the water 2–3 m from shore the night before the sampling period. We also recorded any sightings of turtles moving across land during each sampling period.

Reproductive ecology.—The time period when females were gravid was determined by inguinal palpation (Pritchard and Trebbau 1984), and the nesting period was determined by the presence of nests in the wild. We searched for nests every 15 d in two consecutive days during only the dry season of the sampling period, totaling 20 d of searching. Turtle nests were located each morning (between 0500 h and 0600 h) by following tracks left by nesting females in the sand. We measured the eggs (length and width) of one nest found intact to the nearest mm using dial calipers. The period of hatchling emergence of both species was determined by the presence of hatchlings in traps of local fishermen. All hatchlings caught were measured. They were identified as hatchlings by their thin carapace, caruncle, and lack of growth rings.

Analysis of population structure.—Population structure of the two species was estimated by quantifying the distribution of number of individuals in different size classes and sexes throughout the year. All animals were measured using straight-line maximum carapace length (SCL) and plastron lengths to the nearest mm with calipers**,** sexed, and marked with a unique cut in the center of the marginal scutes (Cagle 1939). All turtles were immediately released at their point of capture after processing. Turtles were individually marked as part of an ongoing research project. The sex of the animals was determined by examination of tail length (for both species) and plastron concavity (only for *K. scorpioides*) (Pritchard and Trebbau 1984) and, for analysis of size distribution the individuals from each species were grouped into 1 cm size classes. A one-way ANOVA was used to determine whether there was a significant difference in mean size (CL) between males and females in each species. The overall sex ratio was compared to an expected sex ratio of unity using a chi-square test. We had no reason to suspect that this population exhibited a 1:1 ratio, and were merely using the 1:1 ratio as a reference point for comparison. All statistical analyses were performed with STATISTIC v. 6.0 (Statsoft 2001) and according to Sokal and Rohlf 1981.

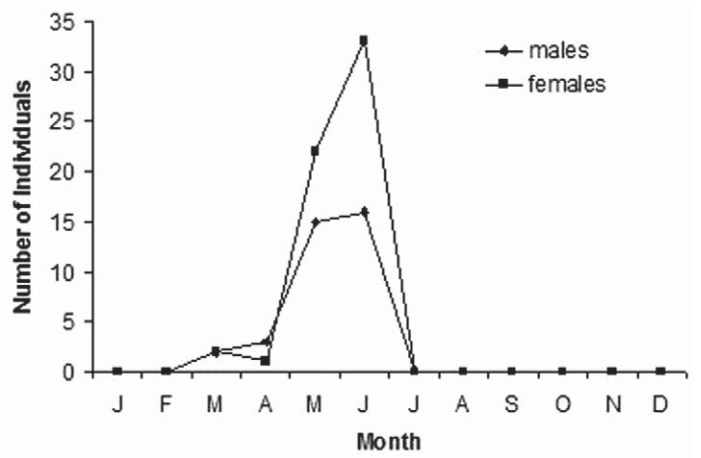

FIG. 1. Number of male and female *Kinosternon scorpioides* captured by month during the sampling period from August 2000 to March 2002.

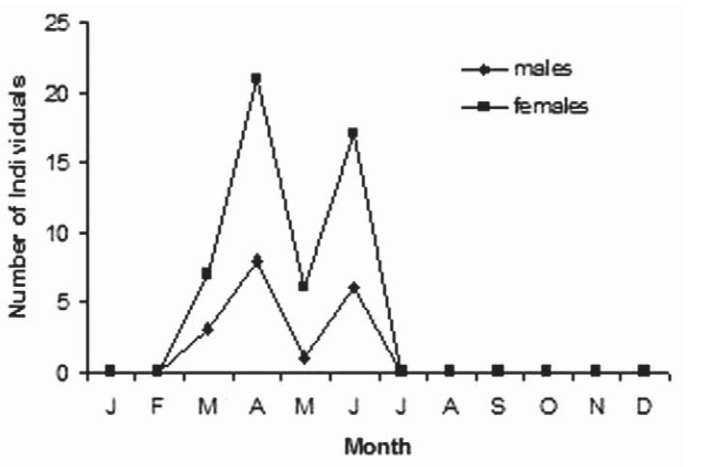

FIG. 2. Number of male and female *Trachemys adiutrix* captured by month during the sampling period from August 2000 to March 2002.

We separated mature and immature individuals for the two species based on the minimum size of carapace length of gravid females found in this study, supplemented with information in the literature from closely related species (e.g., Bager 2003; Iverson 1986; Pritchard and Trebbau 1984) and unpublished data of a specialist (R. Vogt). Adult female *Kinosternon scorpiodes* are sexually mature at 10.4 cm CL and males are mature at 10.1 cm in the Yucatan Peninsula of Mexico (R. Vogt, pers. comm.). *Trachemys adiutrix* are considered adults in seasonal lakes when males reach 9.9 cm CL and females 10.1, in permanent lakes when males reach 13.7 cm and females reach 16.5 cm (Batistella 2008). For this study, we considered an age estimation of maturity for *K. scorpioides* and *T. adiutrix* individuals with minimum carapace length of 10.0 cm for males and females.

RESULTS AND DISCUSSION

Turtles were observed crossing dunes, in grassy areas, and in the bottom of lagoons. The bottom of the lagoons are full of organic material and mud. Individuals of both species were observed throughout the sampling period walking across dunes during the early morning (0600 h) and late afternoon (1800 h).

Gravid turtles were captured during August (N = 38 for *K. scorpioides*; N = 4 for *T. adiutrix*). We found gravid females with maximum and minimum carapace length sizes of 13.7 and 10.0 cm for *K. scorpioides*, and 15.0 and 12.8 cm for *T. adiutrix*, respectively. Fifteen nests were observed in the study area, but identification to species was not possible because the nests had been ravaged by predators (probably foxes, *Cerdocyon thous*, T. Oliveira, pers. comm.). The nests were observed in grassy areas 15–20 m from water. All nests were found between August and

December, during the dry season, with the greatest number being recorded in October and December (N = 7 and 5, respectively). In October 2001, one intact *T. adiutrix* nest was found. This nest was in sandy substrate shaded by grass, was 9.4 cm deep and 11.5 cm in diameter, and contained six elongated eggs with parchment-like shells. Mean egg size was 3.8 ± 0.08 cm (3.7–3.9) in length and 2.4 ± 0.04 (2.4–2.5) in width.

Three *K. scorpioides* hatchlings had a mean carapace length of 3.5 ± 0.07 cm (3.47–3.61). Hatchling *T. adiutrix* (N = 23) had a mean SCL of 3.5 ± 0.2 cm (2.79–3.78). All of these hatchlings were captured in January and February.

We captured 109 *K. scorpioides*; the overall sex ratio (45 females: 35 males = 1.28) did not differ significantly from unity (χ^2 = 4.24, df = 3, P = 0.23). We captured 69 T. adiutrix; 20 females and 15 males. The overall sex ratio was 1.34:1, again not significantly different from unity (χ^2 = 11.83, df = 6, P = 0.06) (see Figs. 1–2 for details). The most abundant size class of *K. scorpioides* was the 11–12 cm size class, and for *T. adiutrix* in the 8, 9, and 15 cm size class (Figs. 3 and 4, respectively). Male *K. scorpioides* were significantly larger than females (F = 12.57, df = 39, P = 0.001). There was no significant difference in size between male and female *T. adiutrix* (F = 0.66, df = 23, P = 0.42).

In our study, hatchling *K. scorpioides* had a mean CL of 3.5 cm and were observed at the onset of the rainy season. We suspect that larger hatchlings had grown prior to first capture because smaller hatchling sizes have been reported than those observed in our study (see Pritchard and Trebbau 1984). Rocha and Molina (1990) reported a mean CL of 2.85 cm for hatchlings incubated in captivity.

In the coastal area of Maranhão State, Vanzolini (1995) observed that *T. adiutrix* laid its eggs in sand close to the water, similar to our observations. Molina (1996) observed that *T. dorbignyi* females in captivity preferred to lay their eggs in a predominantly sandy substrate and in areas without vegetation. The nesting period of *T. dorbignyi* in captivity extends from August to January with the majority of egg laying being concentrated in October and November (Molina 1995, 1996). Rocha and Molina (1990) observed that the nesting period of *K. scorpioides* in captivity lasted from March to August during the dry season. In our study area, the majority of nests were discovered during October and December during the dry season.

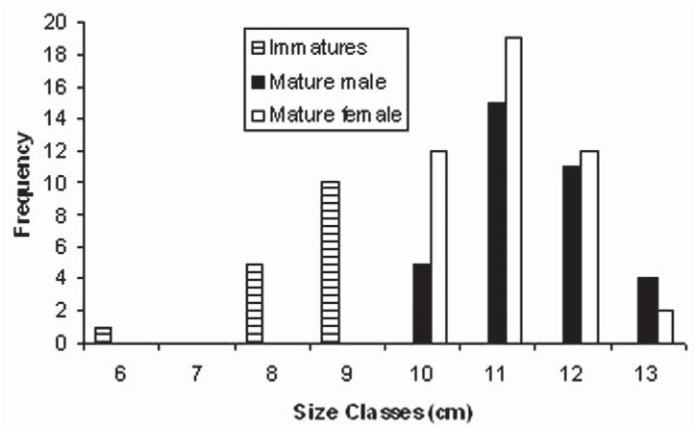

FIG. 3. Size distribution of *Kinosternon scorpioides* at Curupu Island, Maranhão, Brazil from turtles trapped January 2001 to December 2002.

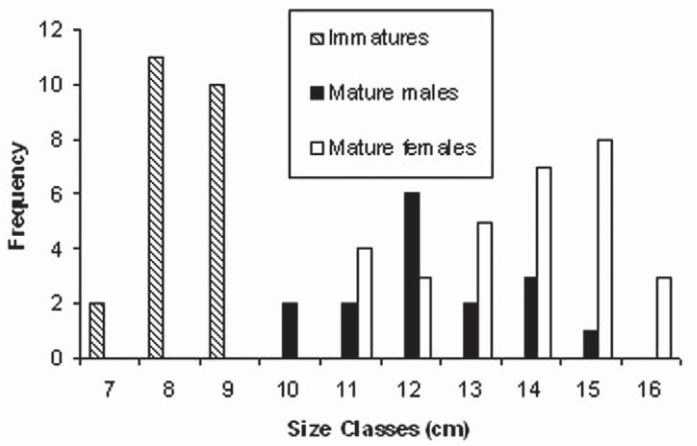

FIG. 4. Size distribution of *Trachemys adiutrix* at Curupu Island, Maranhão, Brazil from turtles trapped January 2001 to December 2002.

The relatively small maximum size of *T. adiutrix* (16 cm) can probably be linked to the hunting of these animals by local people in the study area on Curupu Island, and not because the entrance of the traps prohibited catching larger turtles. In Curupu, because larger sizes of *T. adiutrix* are targeted for their meat, hunting may remove the largest animals from the population. In another locality (Caju Island in Maranhão State) where there is no turtle hunting, we found turtles larger than 21 cm (L. Barreto, pers. obs.).

Acknowledgments.—Richard C. Vogt and two anonymous revisers provided valuable comments on the manuscript. We thank Conselho Nacional de Pesquisa (CNPq) for its financial support during the project in the form of a scholarship. We thank A. C. L. de Castro for statistical analyses and Claudio Gomes, Tiago Ramos, and Anderson Magalhães for field support. Thomas Pedersen improved the digital art (graphic) files. The conservation of animal species relies on the identification and protection of suitable habitat. While general habitat features are important to the success of vertebrate ectotherms because they provide structures for thermoregulation (Blouin-Demers and Weatherhead 2001; Downes and Shine 1998) and predator avoidance (Spencer 2002), biotic elements such as food resource use and distribution are often overlooked in studies of habitat selection. Qualitative descriptions of diet do little to further the understanding of resource use and requirements, which ultimately affect the fitness of individuals. The recent use of stable isotope analysis has shed light on the relationship between foraging ecology and nutrient assimilation in some turtle species (Aresco and James 2005; Bulte and Blouin-Demers 2008; Hatase et al. 2006; Seminoff et al. 2007). Detailed observations of species-specific foraging behavior assist in the implementation of stable isotope analysis by focusing sampling efforts on likely prey, reducing potential costs and time spent in the field.

The Spotted Turtle (*Clemmys guttata*) is a species for which diet and foraging behavior have been qualitatively described (Ernst 1976; Milam and Melvin 2001; Surface 1908). Stomach content analyses of 27 Spotted Turtles revealed three individuals with plant material, while all individuals contained aquatic and terrestrial invertebrates in their guts (Surface 1908). These findings were supported by Ernst's (1976) observations of Spotted Turtles ingesting both plant and animal materials. Spotted Turtles are noted to be opportunistic omnivores, with a highly variable list of diet items including cranberries, earthworms, aquatic insect larvae, crustaceans, snails, salamanders, fish, birds, algae, and tadpoles (Ernst 1976). The relative importance of these food items has not been reported. Spotted Turtles are cold-tolerant and most active in the early spring (Ernst 1976, 1982; Haxton and Berrill 1999; Litzgus and Mousseau 2004; Milam and Melvin 2001; Ward et al. 1976), but they have not been recorded foraging in water cooler than 14°C (Ernst 1976). The broad distribution of this species, as well as differing habitat use between northern and southern populations (Haxton and Berrill 1999; Litzgus and Mousseau 2004; Milam and Melvin 2001; Ward et al. 1976), indicate that detailed dietary and foraging choices should be documented to further our understanding of resource use and habitat selection. In Canada, Spotted Turtles are listed as an endangered species (COSEWIC 2004), and declines and local extirpations have been documented within Ontario despite habitat protection (Browne and Hecnar 2007). Recovery plans should take into account resource distribution, as well as general habitat qualities, in order to create effective management guidelines for this species. The purpose of our study was to quantify dietary choices in a population of Spotted Turtles and describe foraging behaviours observed in natural settings.

Materials and Methods.—The foraging ecology of Spotted Turtles in a population on the shores of Lake Huron in Ontario, Canada was documented during a radio telemetry study in 2007 and 2008. The study site consists of a 95-ha mosaic of Great Lakes coastal wetlands bounded by forested swamps, upland forests, and minimal human development. One hundred and seventeen individuals (54 females, 49 males, 14 juveniles) were captured and marked (Cagle 1939), with an equal distribution of adult males and females ($\chi^2 = 0.24$, df = 1, $p > 0.05$). Fifteen individuals (5 males, 10 females) were located 2–4 times a week from April to August 2007 and 2008 using radio telemetry, with up to 16 additional females located daily during June of both years. Transmitters (SI-2F and SI-2T, 12g, Holohil Systems Ltd, Carp, Ontario) were attached to the rear marginal scutes using copper wire and putty epoxy. Turtles without transmitters were also observed opportunistically. Behavior was characterized for each turtle sighting over the entire study period. Foraging behavior was defined as any aquatic or semi-aquatic activity in which the turtle was actively searching, grabbing, or biting at items. Target items were identified by observing the item during the foraging period, and any unidentifiable items were recorded as "unknown." For each individual turtle observed foraging, ambient air (10 cm from the ground in shade), substrate surface (direct sunlight on substrate), and water temperature (mid-depth of water column) were measured to 0.1°C using a digital thermometer. Temperature-sensitive transmitters allowed the estimation of turtle body temperature from the pulse rate.

Results.—Two hundred and twenty-seven foraging observations were made during the study (Table 1), all within 2–40 cm of water. The greatest proportion of foraging observations were of turtles taking aquatic invertebrates (74%), followed by fish (~16%). Foraging was observed throughout the active season (April to Au-

gust) in both years; however, observations of foraging were more numerous in the earlier months (Fig. 1). While the number of observers (MLR and JEP) remained constant over both years of the study, it is likely that experience gained in 2007 contributed to an increase in overall sightings in 2008. To account for this, monthly observations are presented as percentages of the total observations per year (Fig. 1).

In 2007, water temperatures recorded during foraging ranged from 13°C to 33.8°C. In 2008, water temperatures ranged from 7.7°C to 31.7°C. For individuals outfitted with radio transmitters in 2008, estimated body temperature during foraging ranged from 9.9°C to 31.9°C. Prey items chosen were not related to differences in water temperatures ($F = 0.44$, $df = 3,164$, $p = 0.72$) or estimated turtle body temperatures ($F = 0.09$, $df = 3,113$, $p = 0.96$).

TABLE 1. Observations of foraging by Spotted Turtles (*Clemmys guttata*) in Ontario, Canada over the course of a two-year (2007, 2008) radio telemetry study. Targets indicated by * were consumed as carrion.

Target Item	2007	2008	Total	% of Foraging Observations (excluding unidentified targets)
Aquatic Invertebrates Total	13	19	32	74.0
Freshwater snails	8	8	16	37.2
Trichoptera	1	4	5	11.6
Leech	1	0	1	2.3
Crayfish	1	0	1	2.3
Unidentified	2	7	9	20.9
Vegetation	0	1	1	2.3
Rainbow Trout (*Onchorhynchus mykiss*)*	0	1	1	2.3
Carp (*Cyprinus carpio*)*	0	2	2	4.6
Small Ciprinids and other minnows*	2	2	4	9.3
Leopard Frog (*Rana* [*Lithobates*] *pipiens*)*	1	0	1	2.3
Tadpoles (*Bufo* [*Anaxyrus*] *americanus*)	0	1	1	2.3

Discussion.—The large proportion of invertebrates in Spotted Turtle diets observed in our study agrees with findings of the stomach content analysis by Surface (1908), and foraging observations by Ernst (1976). When consuming hard-shelled snails, individuals would repeatedly bite and release the snail, eventually consuming the soft body and discarding the hard shell. While the majority of animal materials were assumed to be consumed post-mortem, tadpoles were consumed live. Stomach content analysis by Surface (1908) indicated the presence of land-dwelling invertebrates. Whether these items were captured on land or accidentally fell into the water was unknown. Foraging for terrestrial prey was confirmed once during our study. An individual male was observed in shallow water (3 cm) positioning himself vertically using his front legs, and biting at the remains of a spider's web hung between short rushes. Capture and consumption of the spider or items in the spider web was not directly observed. This observation would suggest that while Spotted Turtles are confined to consuming prey items aquatically, these prey items could be captured in a terrestrial environment.

Observations of foraging behavior were most numerous in May, June, and July, with few observations in August (Fig. 1). Foraging is probably most important in early spring after emergence from hibernation, and during the mating and nesting seasons. The energetic demands of sperm production, egg production, copulation, and nesting (Hughes and Brooks 2006; Morreale et al. 1984; Pearse and Avise 2001) require a large effort to be expended in resource gathering early in the season for turtles at northern latitudes. The lack of foraging observations in August could be due to periods of inactivity. Aestivation has been observed in Spotted Turtles and is thought to conserve energy and water during high temperatures in the summer months (Ernst 1982; Perillo 1997). However, temperature data gathered in one Ontario population documented that inactive individuals were not choosing cooler microclimates, and therefore may not be aestivating (Litzgus and Brooks 2000). Alternatively, higher August temperatures may allow turtles to forage in more heavily-vegetated waters reducing our ability to observe foraging behavior later in the season. Capital energy acquired during foraging late in the summer may help supplement income energy gains during the limited time available for foraging between emergence and reproductive activities the following year (Gregory 2006).

Prior to our study, Spotted Turtles were not recorded foraging in waters cooler than 14°C (Ernst 1976). In both years, we observed individuals foraging in water cooler than this minimum. In 2007, we observed foraging at 13°C and made multiple observations of foraging in water temperatures as low as 7.7°C in 2008. We

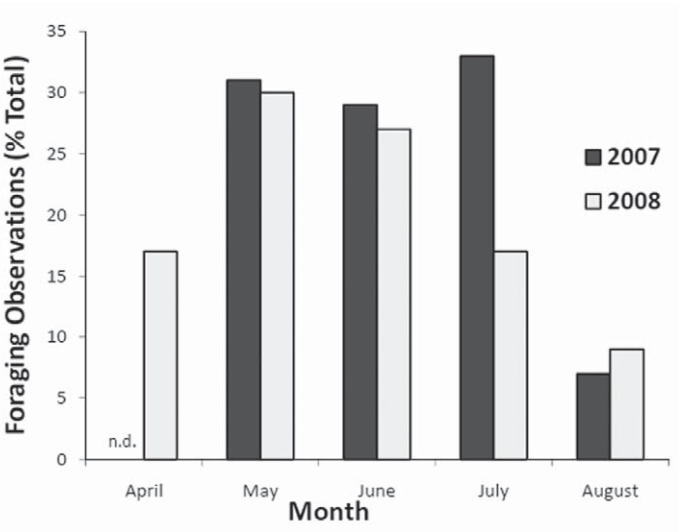

FIG. 1. The percentage of foraging behavior observations for Spotted Turtles (*Clemmys guttata*) in Ontario, Canada for the active seasons of 2007 (black, N = 58 observations) and 2008 (white, N = 170 observations). In April 2007, a lack of researcher presence resulted in no data being collected, denoted as "n.d." on the graph.

did not detect prey choice differences at different environmental temperatures, and this can be explained by the apparently opportunistic nature of foraging. The ability of Spotted Turtles to forage at low temperatures may give them a fitness advantage in the unpredictable and short active seasons typical of northern climates. The acquisition of resources during the active season is vital to an individual's survival from year to year, and also to their ability to produce offspring (Litzgus and Brooks 1998; Litzgus et al. 2008). If Spotted Turtles are restricted by variable water levels in their shallow wetland habitats, then the ability to forage successfully in the cooler months of April and May would certainly be advantageous.

Our study quantitatively highlights the relative importance of food items in the diet of a population of Spotted Turtles. The importance of vegetative matter in Spotted Turtle diets, at least in our population, appears to be minimal. Close observation revealed that although they may appear to be targeting aquatic vegetation, it is in fact most likely that individuals are seeking small freshwater snails and benthic invertebrates within the matrix of aquatic vegetation. This vegetative material may not contribute to energy stores. Stable isotope analysis combined with stomach content analysis in Snapping Turtles (*Chelydra serpentina*) showed that although large amounts of vegetation may be found within the stomach, little of this is translated into tissues (Aresco and James 2005). It appears as though Spotted Turtles are most dependent on macroinvertebrates, with a strong tendency to detect and consume carrion. Future studies of Spotted Turtle foraging ecology should examine the importance of various diet items through stomach content analysis coupled with radio-isotope analysis to explore the relative importance of various food items in tissues, as well as the turtle's trophic position in aquatic ecosystems. This information should be used to supplement habitat selection studies in dictating protection and enhancement guidelines for the continued presence of this species in our ecosystems.

Acknowledgments.—All work was conducted in compliance with CCAC guidelines and under approved Laurentian University Animal Care Protocol #2004-11-01. We thank the local landowners for allowing us access to their land. The research was supported by funding from Ontario Power Generation and NSERC.

Herpetofaunal Conservation in the Rainforest: Perceptions of Ecotourists

TIFFANY M. DOAN
Department of Biology, Central Connecticut State University
1615 Stanley Street, New Britain, Connecticut 06050, USA
e-mail: tiffperu@yahoo.com

The Tambopata region of Peru has the highest overall species diversity of reptiles and amphibians recorded in the world (Doan and Arizábal 2002). Notable amphibians include five species of poison dart frogs and 45 tree frog species (Doan and Arizábal 2002). Three large reptile species are under threat of extinction due to harvesting for eggs or skins: the black caiman (*Melanosuchus niger*), the spectacled caiman (*Caiman crocodilus*), and the yellow-spotted river turtle (*Podocnemis unifilis*) (Kirkby et al. 2000). Ecotourists visiting the Tambopata region have the opportunity to see many herpetofaunal species during their visit.

The rise of ecotourism in Latin America has brought a mix of benefits and problems for local people, national economies, and natural habitats (Groom et al. 1991). In the Tambopata region of Peru, the number of rainforest tourist lodges has increased greatly in recent years, with a corresponding influx of foreign visitors (Groom et al. 1991; Kirkby 2002). As tourist lodges seek greater profits by attracting more visitors, the local habitats may be stressed or altered (Doan 2000; Fennell 1999; Grossberg et al. 2003; Mieczkowski 1995; Orams 2002; Wheeler 1997). Moreover, tourist operations may affect the behavior (Arianoutsou, 1988; Grossberg et al. 2003) or populations (Kirkby and Cornejo Farfán 2000) of fauna in an attempt to create a memorable experience for visitors. Offering guided hikes into the rainforest and boat journeys on rivers allows tourists to encounter many animal species. In some cases guides or other lodge personnel may capture certain animals so that tourists can observe the animals up close. In most cases the animals are then released back into their natural habitat. In addition, many tourist operators capture and restrain animals so that they remain near the lodge, forming a zoo-like atmosphere for personal encounters with animal species (Orams 2002; pers. observ.). Capturing, restraining, and provisioning wild animals have been hypothesized to be detrimental to wild animal populations (Orams 2002).

The practice of capturing or caging animals at ecotourist lodges may have two impacts on the rainforest experience of the ecotourists that visit such lodges. The first effect would be a positive one, where the tourist is able to view animals that are not easily viewed or view animals at close proximity that are normally wary of the presence of humans. In this case, the tourism experience is enhanced by close contact with animals. However, as many international ecotourists are well educated, environmentally conscious individuals (Sekercioglu 2002), it is possible that the practices of capturing and provisioning animals would be perceived negatively, because tourists may be aware of the potential detrimental effects on the captive or tame animals and their populations.

The perceptions of ecotourists toward the treatment of wild animals may differ depending on the animal group concerned. Tourists are thought to have deep affection for animals such as monkeys and birds, but lower affection for less desirable animals such as turtles or frogs (Pough et al. 2004; Tremblay 2002). Many bird watchers are content to devote much time and money to viewing interesting bird species. Moreover, the thoughts of ecotourists about the conservation status of less desirable animals such as reptiles and amphibians may be far removed from their feelings about well-liked mammals and birds. Tourists who are highly concerned about the well being of mammals and birds may have little or no interest or concern for reptiles and amphibians.

Tambopata, Peru currently has twelve large tourist lodges lining the Madre de Dios and Tambopata Rivers, in addition to several smaller lodges (Kirkby 2002). Among these lodges, the policies and practices of capturing, restraining, and provisioning wild animals differ from an absolute ban on these practices, to common use of such practices, including the viewing of captive and tame animals as one of the primary foci of the rainforest lodge experience. As pointed out by Budowski (1976), ecotourists may not always be lucky enough to encounter the large charismatic mammals or birds that they wish to see, but they have a good chance to see the smaller creatures, such as reptiles and amphibians. To determine if the conservation practices of rainforest tourist lodges in southeastern Peru matched the wishes of their ecotourists, tourists were requested to fill out a questionnaire that queried their attitudes towards a rather unpopular group of animals: reptiles and amphibians.

Methods

Study Area.—The study took place in the Tambopata Province of the Madre de Dios Department of southeastern Peru. The four tourist lodges included in the study lie in the buffer zone surrounding the Reserva Nacional Tambopata. This region has seen a marked increase in tourism in the past 25 years and tourism has become one of the most important industries for the region (Groom et al. 1991; Kirkby 2002). The habitat in the Tambopata Province is classified as a Tropical/Subtropical Moist Forest according to the Holdridge system (Gentry and León 1997; Holdridge et al. 1971) and receives an average of 2400 mm of rain annually (Duellman 2005).

The majority of tour visits to each of the four lodges last two nights, although longer tours are available. A typical tour package includes retrieval of the visitors at the airport in Puerto Maldonado on the first morning, followed by bus and boat transport to the lodge. An orientation talk and afternoon hike complete the first day. The second morning guides take groups out for a longer hike that may include a canoe ride on an oxbow lake. The second afternoon is typically free and the second night may offer a lecture by one of the guides or visiting scientists and/or a boat excursion on the river to view caimans, other nocturnal wildlife, and the stars. During the nocturnal boat trip guides may capture small caimans and bring them aboard the boat to show the tourists, after which the caimans are released back into the river. The next morning the tourists are taken back to the airport for their return flight to Cusco or Lima.

Ecotourist Questionnaire.—During 1997 and 1998 tourists at four ecotourism lodges in the Tambopata Province, Peru were asked to fill out a questionnaire during the last night of their rainforest visit. Both English and Spanish versions of the

questionnaire were offered. All guests were invited to fill out the questionnaire but a small percentage (<5%) declined to partake in the survey. The four lodges were: EcoAmazonía (EA) and Reserva Amazónica (RA; formerly named Cuzco Amazónico; Duellman and Koechlin 1991) on the Madre de Dios River and Explorer's Inn (EI; Erwin 1984) and Libertador Tambopata Lodge (LTL; formerly named Tambopata Jungle Lodge; Yu et al. 1997) on the Tambopata River. The questionnaire asked tourists to rate familiarity, viewing desirability, and feelings about the conservation status of the avifauna and herpetofauna (bird questionnaire results are not presented in this paper). They were additionally asked if they would like the lodges to capture animals during guided trips or to keep animals as pets of the lodge. The herpetofaunal portion of the English questionnaire is depicted in Figure 1.

Not all respondents answered every question; therefore, the results of each question are based on different total numbers. Chi-square goodness-of-fit statistical tests were conducted for question numbers 16–23. For each of these, the number of agree and strongly agree responses were tested versus disagree and strongly disagree responses. For these statistical tests, neutral responses were not used (they were a miniscule fraction of responses on most questions). Chi-square tests were also used for question 24, with one test used to determine if there were significant differences in "1" responses (largest threat) and another test used to determine if there were differences in "6" responses (least threat).

Results

In total 129 questionnaires were filled out by ecotourists at the four sites included in the study (EA 26; RA 14; EI 13; LTL 26; the remainder did not indicate which lodge they had visited). Nineteen of the questionnaires completed were the Spanish version and 110 were the English version. Ecotourists that filled out questionnaires ranged in age from 14–82 years and were from 17 different countries (Argentina, Australia, Belgium, Canada, France, Germany, Ireland, Israel, Italy, Luxemburg, The Netherlands, New Zealand, Peru, Spain, Switzerland, United Kingdom, and United States). The mean age of the respondents was 41.2 years and the most common nationalities were United States (29.09%), Australia (16.36%), Canada (12.73%), and the United Kingdom (10.00%). All other nationalities were represented by less than 10 respondents. Of the tourists that indicated their gender, 56 were male and 56 female. Thirty-two respondents (28.6%) stated that they have a scientific background or qualifications. A summary of the questionnaire results is given in Table 1.

Familiarity and Local Experience.—Out of the reptile and amphibian groups about which tourists were asked to rate familiarity, tree frogs were the most familiar animals. Tourists were least familiar with poison dart frogs and coral snakes. Tourists claimed to have seen a wide variety of reptiles and amphibians during their stay. Although crocodiles do not occur in the area, four tourists claimed to have seen both caimans and crocodiles during their lodge visit.

Desire to View.—Tourists wished to see a large variety of reptiles and amphibians. The most popular animals were caimans, followed closely by boa constrictors, but no tourist wished to see venomous snakes and two respondents stated they did not wish to see any reptiles or amphibians at all.

When asked if they would like to see more reptiles and amphibians than they had seen during their stay, the large majority of tourists stated that they would. The difference between respondents who answered agree or strongly agree versus those who answered disagree or strongly disagree was highly significant, both for amphibians and reptiles.

Although not regularly offered by any of the lodges included in this study (but sometimes offered on an ad hoc basis), the large majority of tourists (91.1%) would like to participate in a night hike to view nocturnal animals, including most reptiles and amphibians.

Caiman Viewing.—Just over half (59.8%) of tourists who responded participated in a nocturnal boat journey to view caimans (primarily spectacled caimans, *Caiman crocodilus*). All of the respondents to this question (n = 67) but one saw caimans during their trip. The number of caimans seen by individuals ranged from one to ten.

Pets and Capture of Reptiles and Amphibians.—Contrary to the beliefs of most of the lodge operators and guides (pers. comm.), the large majority of tourists (91.8%) did not wish to see reptiles and amphibians kept as pets and did not approve (94.2%) of guides capturing caimans during the nocturnal boat ride.

Conservation.—The large majority of tourists (95.4%) agreed that reptile and amphibian conservation is as important as bird and mammal conservation and perceived that deforestation was seen as the most important threat (57.1% ranked it number 1), whereas tourism and global warming were seen as least threatening to reptile and amphibian species (41.9% and 32.4%, respectively, ranked them number 6).

More Information Needed.—Seventy-three percent of responding tourists felt that they needed additional information regarding venomous snakes in the area. Suggestions by the lodge tourists were a nighttime presentation in the dining room and that in general more information about all snakes, both venomous and nonvenomous, would be welcome.

Discussion

The highly significant results of this study were remarkable. Contrary to expectations and the beliefs of tourist operators at the four lodges included in this study, visitors had strong interest in reptiles and amphibians. Despite their low level of familiarity prior to the visit, nearly all visitors expressed interest in observing more reptiles and amphibians, and most tourists wished to participate in a night hike. None of the four tourist lodges included in this study regularly offer night hikes to their visitors. Tourist operators may think that tourists would rather rest at night or would be fearful of walking in the forest at night, but the results of this study clearly show the contrary. Tourist operators could increase the unique experience of the rainforest visit for their tourists by offering night hikes, allowing their guests to see not only many more amphibians and reptiles, but also give them the chance to see other nocturnal animals, such as tarantulas, opossums, bats, and owls. Also, tourists would have the opportunity to understand the differences in the ecology of nocturnal animals versus diurnal ones.

A significant majority of visitors would like to view more reptiles and amphibians in their natural setting and did not wish to have

Project Tambopata Ecotourism Questionnaire

13). Which groups of reptiles and amphibians are you familiar with? Circle all that apply.

Tree Frogs	Crocodiles
Pit Vipers	Poison Dart Frogs
River Turtles	Boa Constrictors
Caimans	Coral Snakes

14). Which reptiles and amphibians did you see during your stay at the lodge? Circle all that apply.

Turtles	Venomous Snakes
Lizards	Crocodiles
Nonvenomous Snakes	Tree Frogs
Poison Dart Frogs	Caimans

15). Which reptiles and amphibians would you most like to see during your stay at the lodge? (Please rank: 1=most like to see, 9=least like to see).

Caimans	Boa Constrictors
Poison Dart Frogs	Turtles
Venomous Snakes	Crocodiles
Tree Frogs	Lizards
No Reptiles or Amphibians	

16). Did you participate in a nighttime boat ride to view caimans? YES NO

17). If so, did you see caimans during the trip? YES NO
How many?

For Statements 18-23, mark 1-5 where:

1=Strongly Agree	4=Disagree
2=Agree	5=Strongly Disagree
3=Neutral	

18). I would like to see more amphibians.
19). I would like to see more reptiles.
20). The lodge should keep captive reptiles and amphibians for viewing by the tourists.
21). If it were offered by the lodge, I would like to go on a night walk in the forest to see night-active reptiles and amphibians.
22). The lodge should capture caimans during the nighttime caiman viewing session so that the tourists can see them better.
23). Endangered reptiles and amphibians should be protected as endangered mammals and birds are.

24). What are the biggest threats to reptile and amphibian species in the rainforest (Please rank: 1=largest threat, 6=least threat).

Deforestation	Hunting
Collection for Pet Trade	Water Pollution
Tourism	Global Warming

25). Do you think that there should be more information available about venomous snakes in the area? YES NO
Why?

26). Are you male or female?

27). What is your age?

28). What is your nationality?

29). Which lodge did you visit?

30). Are you a bird watcher? YES NO

31). Do you have any scientific background or qualifications? YES NO

Thank you for taking part in this questionnaire!

PROJECT TAMBOPATA, TRES-RAMOS, CASILLA 28, PUERTO MALDONADO, PERU

FIG. 1. The English language version of the herpetofaunal questionnaire. Questions 1–12 surveyed the tourists about birds and are not included in this study.

TABLE 1. Results of select questions of the questionnaire. *n* is total responding for each question.

Question	*Answers*				*n*	χ^2	*p*
Tourists are familiar with:	Tree Frogs	81	Crocodiles	76	105		
	Pit Vipers	40	Poison Dart Frogs	27			
	River Turtles	68	Boa Constrictors	71			
	Caimans	72	Coral Snakes	35			
During their stay tourists saw:	Caimans	85	Nonvenomous snakes	25	109		
	Turtles	68	Poison dart frogs	10			
	Lizards	67	Venomous snakes	5			
	Tree frogs	44	Crocodiles	4			
Tourists would most like to see:	Caimans	39	Crocodiles	4	104		
	Boa constrictors	25	Lizards	1			
	Poison dart frogs	9	Venomous snakes	0			
	Tree frogs	6	No reptiles or amphibians	2			
	Turtles	6					
Tourists would like to see more amphibians:	Strongly agree	49	Disagree	0	109	90.000	< 0.001
	Agree	41	Strongly disagree	0			
	Neutral	19					
Tourists would like to see more reptiles:	Strongly agree	48	Disagree	4	110	72.516	< 0.001
	Agree	41	Strongly disagree	2			
	Neutral	15					
Tourists would like to participate in a night walk:	Strongly agree	42	Disagree	4	112	60.844	< 0.001
	Agree	40	Strongly disagree	4			
	Neutral	22					
The lodge should keep captive reptiles and amphibians:	Strongly agree	4	Disagree	33	110	68.612	< 0.001
	Agree	4	Strongly disagree	57			
	Neutral	12					
The lodge should capture caimans to show the tourists:	Strongly agree	2	Disagree	28	111	80.398	< 0.001
	Agree	4	Strongly disagree	69			
	Neutral	8					
Reptiles and amphibians should be as protected as birds and mammals:	Strongly agree	84	Disagree	1	109	88.926	< 0.001
	Agree	19	Strongly disagree	4			
	Neutral	1					
Largest threat to herpetofaunal conservation:	Deforestation	72	Hunting	13	126	163.333	< 0.001
	Water pollution	23	Global warming	5			
	Collection for pet trade	13	Tourism	0			
Least threat to herpetofaunal conservation:	Tourism	62	Hunting	12	107	119.242	< 0.001
	Global warming	48	Water pollution	10			
	Collection for pet trade	14	Deforestation	2			
Tourists request more information about venomous reptiles:	Yes	73	No	27	100		

them captured or kept as pets. Two of the tourist lodges included in this study (EA and RA) have recently devoted much of their effort into raising animals as pets or attracting them to the lodge with food. Although the animals they currently restrain and attract have been mammals and birds, it is conceivable that they would also keep animals such as tortoises or frogs as pets. The results of this study clearly show that keeping reptiles or amphibians as pets would be contrary to the wishes of the ecotourists.

In addition, respondents were concerned about the conservation of reptiles and amphibians. They cared about the conservation status of these strange, unfamiliar animals, just as they would for more charismatic mammals and birds. Ecotourists considered deforestation to be the most important threat to reptile amphibian conservation by far. Few tourists considered water pollution, collection for the pet trade, hunting, global warming, or tourism to be important threats. While deforestation is obviously an important threat for

all rainforest species (Duellman and Trueb 1986; Laurance and Bierregaard 1997), collection for the pet trade of animals such as boa constrictors, and hunting of caimans and river turtle eggs also are deleterious to local populations (Duellman 2005; Kirkby 2002; Pough et al. 2004). In addition, water pollution has been shown to impact amphibian populations in some areas (Duellman and Trueb 1986; Stebbins and Cohen 1995), and global warming has been hypothesized to be contributing to the global amphibian population decline (Pough et al. 2004; Stebbins and Cohen 1995). Tourists in Tambopata need to receive more education about the potential threats to the herpetofauna to be fully informed about conservation issues affecting local species.

The results of this study seemed to be consistent over all groups of people who responded to the questionnaire—nationalities, genders, and ages, and did not depend upon which lodges the tourists were visiting. This suggests that these results may be broadly applicable to other rainforest lodges and, perhaps, to other areas of the world. Ecotourism has the potential to be a sustainable form of utilizing rainforest resources (Groom et al. 1991; Scace 1993), and the encouraging results of this study suggest that the visitors to Tambopata may contribute to sustainability by promoting responsible ecotourism.

Acknowledgments.—My greatest thanks go to the lodge visitors that agreed to take the time to complete the questionnaire. I would like to thank Huw Lloyd and Wilfredo Arizábal Arriaga for the ideas to begin this study and for help implementing it. I would also like to thank the lodge owners, managers, and guides and EcoAmazonía, Reserva Amazónica, Explorer's Inn, and Libertador Tambopata Lodge for permitting me to conduct the study with their guests. I would like to thank Chris Blair and Carol L. Spencer for their comments on the manuscript. This study was carried out during Project Tambopata, which was funded by the Percy Sladen Memorial Fund, the Tambopata Reserve Society (UK), the Grand Circle Foundation, the Lindeth Charitable Trust, the Albert Reckitt Trust, and the Anglo-Peruvian Society.

Despite having been studied for many years, the status and knowledge of the herpetofauna of Peninsular Malaysia is far from being complete or fully understood. Although relatively recent new species discoveries have added significantly to the overall biodiversity of the region (Chan and Grismer 2008; Chan et al. 2009; Das et al. 2007; Das and Lim 2001; Grismer and Chan 2008; Grismer et al. 2006 and references therein; Grismer et al. 2008a, b, c; Grismer et al. 2009; Grismer and Norhayati 2009; Leong and Lim 2003; Matsui and Jaafar 2006; McLeod and Norhayati 2007; Van Rooijen and Vogel 2008; Vogel and Van Rooijen 2007; Wood et al. 2008, 2009), information on existing species are still inadequate or lacking altogether. Alongside these new findings, intensive and systematic field work has also uncovered a number of rare species (e.g., *Cyrtodactylus sworderi*, Grismer et al. 2007; *Enhydris pahangensis*, Chan, *in press*) which have not been recorded since their discoveries in the early 1900s. Many of these species lack complete descriptions and/or proper color illustrations and next to nothing is known about their life history as they have rarely been observed in the wild. This paper addresses some of these issues by providing expanded descriptions, color photographs, life history observations, and new locality records of the more poorly known frogs and snakes of Peninsular Malaysia.

Materials and Methods

Color photographs were taken for vouchers and color pattern comparisons. Measurements were taken with Mitutoyo digimatic caliper to the nearest 0.1 mm. Measurements taken for frogs are as follows: snout–vent length (SVL); tibia length (TiL), measured from the center of the knee to the centre of the ankle. For snakes: snout–vent length (SVL); tail length (TaL), from cloaca to tail tip; number of dorsal scale rows (DoS), counted at one head length posterior to head, at midbody, and one head length anterior to vent; number of ventral scale rows (Ven); number of supralabials (SupL), with the number of SupL in contact with the orbit in brackets; number of infralabials (InfL). Voucher specimens or photographs are provided to support new locality records. All specimens have been deposited at the museum of the Department of Wildlife and National Parks Peninsular Malaysa (DWNP) and the herpetological collection at Universiti Kebangsaan Malaysia (UKM). HC refers to the Herpetological Collection of Universiti Kebangsaan Malaysia (UKM), Bangi, Selangor, Peninsular Malaysia; UKMDPC refers to Universiti Kebangsaan Malaysia Digital Photograph Collection; LSUDPC refers to the La Sierra University Digital Photograph Collection. Institutional abbreviations follow Leviton et al. (1985), except we retain ZRC for USDZ, following conventional usage. Measurements taken on voucher specimens are presented in Table 1.

Results

Species accounts

Rhacophorus robinsoni Boulenger 1903
Robinson's Treefrog
Fig. 1

Rhacophorus robinsonii Boulenger 1903 *in* Annandale and Robinson (eds.), Fasciculi Malayenses, 2(1):136. Type locality: "Bukit Besar. 2500 feet", Pattani, Thailand.
Rhacophorus (Rhacophorus) robinsonii Ahl 1931:157
Rhacophorus pardalis robinsoni Wolf 1936:208
Rhacophorus robinsoni Inger 1954:372; Berry 1975:109; Manthey & Grossman 1997:138; Das & Norsham 2007:70

Description. SVL male 59 mm; female 82 mm; Vomerine teeth in two long oblique series touching the inner edge of the choanae; snout obtusely pointed; canthus rostralis sharp; tympanum distinct, as high as wide; supratympanic fold distinct, outlined with black, extends horizontally posterior to the orbit, slants, and ends abruptly posterior to the tympanum.

Finger tips expanded into large disks bearing circum-marginal and transverse ventral grooves; width of three outer fingers equal to tympanum diameter; broad webbing reaches base of disks of outer three fingers but only halfway to disk of first finger; nuptial pad present in males. Toe disks smaller than those of fingers, bearing circum-marginal and transverse ventral grooves; completely webbed to disks on all toes; a small inner metatarsal tubercle; no outer metatarsal tubercle.

Skin above smooth; slightly granular on flanks and throat; belly covered with large, smooth, rounded granules; arms and tarsus without flaps of skin; no anal flap.

Color in life. Pale brown or dark chocolate brown to light green above; two thin, black bars on the head, one crossing the snout, and another longer bar between the orbits; dorsum scattered with dark blotches; with or without a white spot below the tympanum; sides of head a darker shade of brown; flanks, inner and outer sides of limbs yellowish with black and whitish-blue reticulations; limbs bearing dark cross-bars; interdigital webbing black with fine brown veins; throat whitish, mottled with brown; belly white with dark reticulations. Juveniles: yellow to orange interdigital webbing; underside of the body yellowish.

Life history. *Rhacophorus robinsoni* inhabits primary or old, undisturbed secondary forests and has been found on tree tops as high as 10 m above the forest floor (Grismer et al. 2004) and on leaves as low as 1 m above the ground. Like many of its other congeners, frogs descend lower to the ground following heavy rainfall to breed along stagnant puddles or ponds. However, one specimen from Ulu Gombak was found sitting on a leaf during an extremely dry night when no other frogs were abroad and Grismer et al. (2004) recorded a gravid female during the day, crouched in

the interstices of truck tracks on a logging road far from any body of water.

Distribution in Peninsular Malaysia. Kuala Teku, Pahang (Berry 1975); Gombak, Selangor (Yong 1977); Temenggor, Perak (Grismer et al. 2004); Cameron Highlands, Pahang; Kampung Chennah, Negeri Sembilan (this report).

Notes. In Peninsular Malaysia, *Rhacophorus robinsoni* has only been recorded three times, the first being from Kuala Teku, Pahang in the early 1900's (Boulenger 1912) and the second from Gombak, Selangor (Yong 1977). A third specimen was reported by Grismer et al. (2004) from Temenggor Forest Reserve, Perak, but was left unidentified (*Rhacophorus* sp.). This species has since been found at Cameron Highlands, Pahang (UKMDPC 1.0002) and Kampung Chennah, Negeri Sembilan (HC 191,192; Fig. 1). Given the current distribution pattern of *R. robinsoni* which ranges from southern Thailand to its southernmost record in Negeri Sembilan, it is likely that this species has a wider distribution range and probably occurs throughout Peninsular Malaysia.

Theloderma leprosa Tschudi 1838
Fig. 2

Theloderma leprosa Tschudi 1838, Classification der Batrachier, 32: 73. Type locality: "Sumatra", Indonesia.
Hyla leprosa Schlegel 1858:55
Theloderma leprosum Boulenger 1884:21
Polypedates leprosus Günther 1887:315
Rhacophorus leprosus Boulenger 1890:324; Berry 1975:100
Theloderma leprosa Das & Norsham 2007: 71

Description. SVL 65 mm; Vomerine teeth in two short series touching the inner front edge of the choanae; head broader than long; canthus rostralis visible, angular; lores distinctly concave; nares protruding from snout with an internarial sulcus; tympanum distinct, ¾ eye diameter, ellipsoidal, covered with small, rounded warts not bearing asperities; supratympanic fold absent. Finger tips expanded into disks bearing circum marginal grooves; fingers free of web; outer metacarpal tubercle present; nuptial pad present in males. Disks of toes smaller than those of fingers, bearing circum marginal grooves; toes nearly entirely webbed, reaching disks of third and fifth, third phalanx of fourth; subarticular tubercles well developed; inner metatarsal tubercle present.

Entire upper surface covered with prominent warts of varying sizes, all bearing granular asperities; a series of large, ridge-like warts on back and hind limbs; throat with raised granules bearing apical asperities; chest and belly covered with large, smooth, rounded granules.

Chocolate to grayish brown above; asperities on warts whitish which gives it a speckled appearance; underside of body, lower side of flanks and inner side of limbs black with whitish and pale blue reticulations; interdigital webbing and disks orange.

Life history. *Theloderma leprosa* has been observed in tree-holes as high as 3 m above ground (pers. obs.) The size of these large thelodermids (Max. SVL 65 mm) may play a role in habitat stratification within this group, with smaller congeners (*T. asperum, T. horridum*, and *T. licin*) and other tree-hole dwellers (*Metaphrynella pollicaris* and *Phrynella pulchra*) occupying smaller tree holes and cavities closer to the ground. Thus far, frogs have only been found in primary and old secondary forests where bigger trees are presumably able to provide the specific microhabitat requirements for these large tree-hole breeders. Berry (1975) noted that a specimen was found in a hole made by cicadas in the ground while Dring (1979) found a specimen on a palm leaf 1.5 m above ground at 790 m in elevation. *Theloderma leprosa* appears to be a high altitude species, occurring at elevations of approximately 800 m and above sea level.

Distribution in Peninsular Malaysia. Bukit Larut, Perak; Gunung Angsi, Negeri Sembilan; Gunung Tapis, Pahang (Berry 1975); Gunung Lawit, Terengganu (Dring 1979); Cameron Highlands, Pahang; Gunung Besar Hantu, Negeri Sembilan (this report).

Notes. *Theloderma leprosa* was first discovered in the Malay Peninsula by Mr. L. Wray from Larut Hills [Bukit Larut], Perak at 4000 feet elevation (Boulenger 1912). Subsequent locality records were from Gunung Angsi, Negeri Sembilan (at 2600 feet) and Gunung Tapis, Pahang (Berry 1975). Dring (1979) reports this species from Gunung Lawit, Terengganu. Since then, this species has also been discovered in Cameron Highlands, Pahang and Gunung Besar Hantu, Negeri Sembilan (HC 281; Fig. 2). Thus far, *T. leprosa* has been shown only to occur at high elevations in all three of Peninsular Malaysia's main mountain ranges, Bukit Larut on Banjaran Bintang; Cameron Highlands, Gunung Besar Hantu and Gunung Angsi on Banjaran Titiwangsa; Gunung Lawit and Gunung Tapis on Banjaran Timur. Following such trends, this species is likely to occur on other mountain tops throughout those mountain ranges.

Hylarana siberu (Dring, McCarthy & Whitten 1990)
Fig. 3

Rana siberu Dring, McCarthy & Whitten 1990. *Indo-Malayan Zoology*, 6(1989): 119-132. Type locality: "Teitei Bulak, Sabeuleleu, Siberut [Island], 1° 21´S, 98° 59´E", Mentawai Islands, Indonesia.
Rana (Pulchrana) siberu Dubois 1992:326
Pulchrana siberu Frost et al. 2006:369
Hylarana siberu Che et al. 2007:1

Description. SVL male 39.5 mm; female 44.9 mm; Skin above smooth, slightly rugose on back, flanks and underside of body. Tympanum visible, slightly higher than wide, about ½ eye diameter; supratympanic fold absent. Nuptial pads absent in males; humeral glands enlarged. Fingers with rudimentary web; outer metatarsal tubercle round, inner one oval. Web reaching one half phalanx of first toe and first phalange of second toe, one half phalanx between second and third toes, base of disk of third toe and second phalanx of fourth toe, two half phalanges between fourth and fifth toes; inner metatarsal tubercle oval. Dorsum completely black without markings; complete or nearly complete reddish/orange dorsolateral stripe from rostrum, along the canthal region, lateral margin of upper eyelid, along body and terminating at sacral region; series of small, white spots on upper labial; flanks and upper side of limbs with round, creamy yellow spots, sometimes connected together forming short, roundish streaks; throat and underside of limbs whitish, heavily stippled with dark brown; belly whitish with dark brown reticulations

Life history. *Hylarana siberu* inhabits lowland primary forest and has been found along the edge of a temporary pool in a swampy area away from streams. Another specimen was caught in a pit-fall trap away from streams as well which may indicate that this species is not a riparian as is its putatively close relative

Hylarana picturata which it most closely resembles.

Distribution in Peninsular Malaysia. Lakum Forest Reserve, Pahang (Leong and Lim 2004); Kuala Gandah, Pahang (this report).

Notes. *Hylarana siberu* was previously known from the Indonesian Island of Siberut (west Sumatra) and Sumatra only (Dring et al. 1990). The first record of this species in Peninsular Malaysia was of a single adult male from the Lakum Forest Reserve, Pahang (Leong and Lim 2004). This paper reports the second known specimen of an adult female (DWNP 1189; Fig. 3) from Kuala Gandah, Pahang, approximately 25 km from Lakum Forest Reserve. In Peninsular Malaysa, *H. siberu* most closely resembles *H. picturata* but differs by having an immaculate dorsum vs. a spotted dorsum; continuous, unbroken dorsolateral stripe vs. discontinuous dorsolateral stripe formed by closely linked spots; and reduction in webbing on toes vs. nearly full webbed.

Reptilia

Calliophis gracilis Gray 1835
Spotted Coral Snake
Fig. 4

Calliophis gracilis Gray 1835. Illustrations of Indian Zoology, chiefly selected from the collection of Major - General Hardwicke. Vol. 2. London (1833–1834): 263 pp.
Callophis gracilis Günther 1864
Elaps nigromaculatus Cantor 1847:1029
Callophis gracilis Boulenger 1912:203
Calliophis gracilis Tweedie 1983:110
Calliophis gracilis Welch 1994:39; Slowinski, Boundy & Lawson 2001

Description. Body slender, relatively long, up to 740 mm total length; tail very short, terminating in a blunt point; dorsal scales arranged in 13/13/13 rows; ventrals 303–324; subcaudals 21–28; six supralabials, 3rd and 4th touching the orbit; five infralabials.

Body gray above with a thin, black, vertebral stripe connected to a series of small black spots. Similar lateral stripe connects a series of larger, black spots which alternate with smaller, vertebral spots. Top of head with dark, symmetrical markings. Underside of body with alternating black and yellow bands. Underside of tail banded black and orange.

Life history. A specimen from Cameron Highlands was found by Orang Asli collectors above 700 m elevation. At Bukit Lagong, Selangor, a subadult specimen was observed in the afternoon, swimming across a dammed-up portion of stream at 350 m elevation.

Distribution in Peninsular Malaysia. Penang, southern Perak, Selangor (Boulenger 1912); Fraser's Hill, Pahang (Leong and Lim 2003); Cameron Highlands, Pahang (this report)

Notes. According to Cantor (1847), *Calliophis gracilis* is common in the hills of Penang but no reports of this species have been made from that island since his early observations. In Selangor, this snake is known from Gombak and Bukit Lagong, Kepong.

Xenelaphis ellipsifer Boulenger 1900
Ocellated Brown Snake
Fig. 5

Xenelaphis ellipsifer Boulenger 1900. Description of new reptiles and batrachians from Bomeo. Proc. Zool. Soc. London: 182–187. Type locality: Sarawak river.
Xenelaphis ellipsifer Tweedie 1983:48; Manthey & Grossmann 1997: 396; Malkmus et al. 2002:369

Description. Maximum recorded length 2320 mm; 1-2 preoculars, one subocular, two postoculars; one loreal; 8-9 supralabials; 2+2 or 1+2 temporals; dorsal scales arranged in 17/17/15 rows; 186–203 ventrals; anal plate divided; 129–134 subcaudals. Brown above, paler on the sides with a series 18-20 black, circular or ellipsoidal markings, each crossing the back and touching the ventrals on either side; the circles are bordered externally with paler brown or white and in between each circle, lower on the sides is an irregularly shaped black spot; top of head and neck rusty brown with longitudinal black markings on side of neck; sides of head and neck yellow; belly creamy white.

Life history. *Xenelaphis ellipsifer* inhabits primary and old secondary forests from lowlands to 1100 m in elevation. Adults probably feed on fish and rodents while juveniles prefer fish, frogs and lizards (Malkmus et al. 2002). According to the Orang Asli collectors who found this species in Kampung Chennah, Negeri Sembilan, the snake was abroad at night, foraging in and along a moderately flowing stream and was quick to escape when approached. The same snake was observed along the same stream a number of instances which might suggest a narrow home range.

Distribution in Peninsular Malaysia. Bukit Larut, Perak; Cameron Highlands, Pahang (Tweedie 1983); Gombak, Selangor (pers. comm.); Kampung Chennah, Negeri Sembilan (this report).

Notes. *Xenelaphis ellipsifer* was not known from Peninsular Malaysia until 1954 when a specimen was found in a collection from Bukit Larut, Perak. It was then the fifth specimen of *X. ellipsifer* known to science, with previous records being from Borneo and Sumatra (Tweedie 1983). Lim (1958) reported a skin obtained from Cameron Highlands in 1957. Since then, *X. ellipsifer* has not been seen until Sheperd and Auliya (pers. comm.) reported a sighting of this species at Gombak, Selangor. Following that, another specimen was found by Orang Asli collectors in the lowland forests of Kampung Chennah, Negeri Sembilan which constitutes a new locality record (HC 194; Fig. 5).

8

Oligodon signatus Wall 1923; Tweedie 1985:53; Hendrickson 1966:67; Manthey & Grossman 1997:373

Description. Maximum length 600 mm; seven supralabials, third and fourth contact orbit; loreal usually present, rarely absent on one side of the head; dorsal scales arranged in 17/15/15 rows; 141–157 ventrals; 47–60 subcaudals. Chocolate brown above with a series of reddish, chevron-like markings mid-dorsally that begin just posterior to the nape until the tip of tail. Markings are spaced approximately 8–10 scales apart at midbody. These markings are larger and more elongate at the anterior portion of the body and decrease in size towards the tail. Underside of body pinkish red.

Life history. This semi-fossorial snake inhabits lowland to upper hill forests.

Distribution in Peninsular Malaysia. Selangor; Malacca (Batchelor 1958); Gunung Panti Forest Reserve, Johor (Yong 2006); Cameron Highlands, Pahang; Kampung Chennah, Negeri Sembilan (This report).

Notes. In Peninsular Malaysia, Batchelor (1958) reports *Oligodon signatus* from Selangor and Malacca. Yong (2006) reports a specimen from Gunung Panti Forest Reserve, Johor, which was positively identified from a roadkill. Two additional localities reported here are Kampung Chennah, Negeri Sembilan (HC 196; Fig. 6) and Cameron Highlands, Pahang (UKMDPC 1.0077). The latter represents the northern most record for this species.

Asthenodipsas malaccanus
Malayan Slug Snake
Fig. 7

Asthenodipsas malaccana Peters 1864. Über neue Amphibien (*Typhloscincus, Typhlops, Asthenodipsas, Ogmodon*). Mber. k. preuss. Akad. Wiss., Berlin: 271–276.
Amblycephalus malaccanus Boulenger 1892; De Rooij 1917
Pareas malaccanus Robinson & Kloss 1920; Grandison 1972, 1978
Internatus malaccanus Rao & Yang 1992
Asthenodipsas malaccanus Iskandar & Colijn 2002; Grossman & Tillack 2004

Description. Body cylindrical with a very weak vertebral ridge; 6–8 supralabials, 3rd and 4th, rarely only 3rd touching orbit; 5–7 infralabials; dorsal scales arranged in 15/15/15 rows; 154–180 ventrals; 26–56 subcaudals. Ground color of dorsal surface of body and tail greyish brown; top and sides of head and supralabials dusky white smudged with irregularly shaped, gray to brown markings; iris red; dull, white, vertebral line extending posteriorly approximately 14 scale rows connects white head markings with first white, dorsal body band; dorsum overlain with approximately 28 irregularly shaped to squarish, white vertebral blotches; some blotches occur only on one or the other side of the vertebral region, covering 3–5 scale rows; others straddle the vertebral region covering 5–7 scale rows; series of broken to continuous white markings on vertebral scales connect dorsal blotches; brown stippling on centralmost scales of blotches give blotches a smudged appearance; sides of body and tail immaculate; infralabials, gular region and throat white with dark grey-brown mottling; ventral scales grayish brown, slightly lighter than color of dorsum; white midventral line extends from throat to tip of tail.

Life history. A gravid female carrying three eggs was found above 800 m elevation on Gunung Besar Hantu, Negeri Sembilan during the month of September (HC 195; Fig. 7).

Distribution in Peninsular Malaysia. Asahan Estate, Malacca; Gunung Benom, Pahang; Perak; Selangor (Tweedie 1983); Endau-Rompin National Park, Johor (LSUDPC 4860); Gunung Besar Hantu, Negeri Sembilan (this report).

Notes. *Asthenodipsas malaccanus* ranges from Thailand, through Peninsular Malaysia to Indonesia (Sumatra and the Mentawai Islands). Stuebing and Inger (1999) reported this species from Borneo, however, we have examined a series of eight specimens of *A. malaccanus* from Thailand, Indonesia, and Peninsular Malaysia, including the holotype (see appendix) and found them to differ notably from the Bornean population by having a weak vertebral ridge vs. a strong ridge; and a blackish dorsum with white, squarish, paravertebral blotches vs. a tan dorsum with dark, vertical bars. Therefore, we consider the *A. malaccanus* of Borneo to be a potentially new species.

Enhydris pahangensis
Pahang Water Snake
Fig. 8

Enhydris pahangensis Tweedie 1946. Tweedie, M.W. F. 1946. A new snake from the Malay Peninsula. Ann. Mag. nat. Hist. (11) 13 (98):142–144.

Description. Males up to 300 mm SVL; females up to 392 mm SVL; dorsal scales arranged in 25/25/21 rows; 129–132 ventrals; 47–55 subcaudals; eight supralabials, 4th touching the orbit; 11 infralabials. Grayish or yellowish brown above with a series of paired, dark spots beginning from the nape to the base of tail. Spots are usually half a scale wide and may not always be parallel to each other. Anterior portion of the head darkly stippled, slightly darker than ground body color. Labials white, heavily stippled with black. A cream-colored lateral stripe on each side of the body extends from the side of the head to the tail tip. On the body, this stripe covers four of the lowest dorsal scale rows, reduced to three towards the vent. The stripe is bordered above and below by a black zig-zag line, the line bordering the ventral scales is thicker and more pronounced. Ventrals white, edged with black, with an antero-medial dark blotch on each ventral scale. Chin scales white, mottled with black.

Life history. This species inhabits primary or undisturbed secondary forests and has been found among decaying leaves in a stagnant portion of a small and slow moving stream.

Distribution in Peninsular Malaysia. Kuala Tahan, Pahang (Tweedie 1983); Sungai Kura, Hulu Terengganu (Chan, *in press*); Nenasi Forest Reserve, Pahang (this report).

Notes. In Peninsular Malaysia, *Enhydris pahangensis* most resembles *E. plumbea* but differs by having 25 dorsal scale rows vs. 19; a creamy lateral stripe distinctly bordered above and below by a black zig-zag line vs. a creamy lateral stripe lacking distinct zig-zag borders; labials, chin scales, and anterior portion of snout mottled with dark gray vs. no mottling; ventral and subcaudal scales white, edged with black and an antero-medial dark blotch on each ventral scale vs. immaculate white. Previously, *E. pahangensis* was only known from the type specimen from Kuala Tahan, Pahang. Subsequently, a second specimen was collected from Hulu Terengganu (Chan, *in press*), thereby expanding its

distribution to the neighboring state. We report of a third locality from Nenasi Forest Reserve, Pahang (HC197, HC198; Fig. 8). Due to its close resemblance to *E. plumbea* whose identity it has probably been masquerading under most of the time, this species is likely to encompass a wider distribution which might be revealed upon closer examination of existing museum specimens.

Discussion

Herpetofaunal surveys generally result in skewed observation frequencies with some species observed much more frequently than others (e.g., Das 1996; Murphy et al. 1994; Ziegler 2002) and several factors can contribute to the perceived rarity of a particular species. First, some species are rarely seen simply because of their association with specific, isolated, habitats like forest canopies, karst formations, mountain tops or islands (e.g., Chan and Grismer 2008; Chan et al. 2009; Grismer and Chan 2008; Grismer 2007, 2008; Grismer et al. 2008a, b, c; Stuebing and Tan 2002). Surveys to these locations are usually more infrequent resulting in fewer reports. Other factors include elusive lifestyles or morphology (nocturnal or fossorial habits and camouflage) and the fact that some species do actually occur in low densities. These factors are difficult to disentangle in practice unless very strict survey methodologies are applied. However, species abundance patterns in many taxa are known to correspond roughly to a log-normal distribution with some species being abundant and many occurring in low densities (e.g., Limpert et al. 2001; Longino et al. 2002; Loreau 1992). Not surprisingly, such uneven species abundance patterns also appear to hold true for reptiles and amphibians. For instance, Lloyd et al. (1968) carried out a very thorough herpetological survey in a lowland rainforest in Sarawak and concluded that the herpetofaunal species abundance is fairly uneven, with other workers coming to similar conclusions (e.g., Dash and Mahanta 1993; Inger and Colwell 1977; Karns et al. 2005).

Knowledge on the herpetofauna of Peninsular Malaysia has seen great progress in recent years with new locality records and new species growing at an unprecedented rate (Chan and Grismer 2008; Chan et al. 2009; Grismer 2008; Grismer and Chan 2008; Grismer and Pan, 2008; Grismer et al. 2004, 2006; Wood et al. 2008, 2009). Such reports are crucial for biogeographic studies and focus on the importance and utilization of regional checklists which are not to be underestimated. Grismer and Pan (2008) highlighted regions of Peninsular Malaysia most understudied and suggested areas where focused research efforts should continue and Grismer et al. (2009) stressed the importance of looking more closely at species that have already been collected. This two-pronged approach to studying the diversity of this region's herpetofauna has already proved invaluable (see the review by Grismer et al. 2009) and will only generate more discoveries as time passes.

Acknowledgments.—We thank L. Lee Grismer and Johan van Rooijen for their critical insights, comments, and contributions.

On the Distribution and Status of *Plectrohyla hazelae* (Taylor, 1940) (Amphibia: Hylidae) from Oaxaca, Mexico

JOSEPH R. MENDELSON III*

Duellman (2001) reviewed and updated the distributional status of all hylid species in Mesoamerica that were known at the time. We examined the updated distributional map for *P. hazelae* (Duellman 2001:fig. 386, and presented here as Fig. 1a). This same geographic information is also reflected on the map accompanying the account of *P. hazelae* appearing on the online IUCN Red List (http://www.iucnredlist.org/), which is the same information compiled by the Global Amphibian Assessment (Stuart et al. 2004). Based on these sources, the prevailing concept of the distribution of this species (Fig. 1a) is that it occurs disjunctly in three montane areas in Guerrero and Oaxaca, Mexico, namely the Sierra Madre del Sur, Sierra Yucuyacua, and Sierra Aloapaneca. The type locality is on Cerro San Felipe, in the Sierra Aloapaneca, and a small number of specimens from various localities on those slopes are deposited in museums; most of these are listed by Duellman (2001:704). A review of available specimens of *P. hazelae* listed by Duellman (2001:1125), however, revealed several misidentified specimens and other problems. The status of some specimens of *P. hazelae* listed by Duellman (2001:1125) is given in Table 1. The specimens from Puerto de Gallo, Sierra Madre del Sur, Guerrero (CAS 143106–07) are referable to *Plectrohyla mykter.* The two records from the vicinity of Putla, Oaxaca (Sierra Yacuyacua) are more problematic. Duellman (2001:1125, fig. 386) listed and mapped two specimens from "16 kilometers southwest of Cuquila" in the

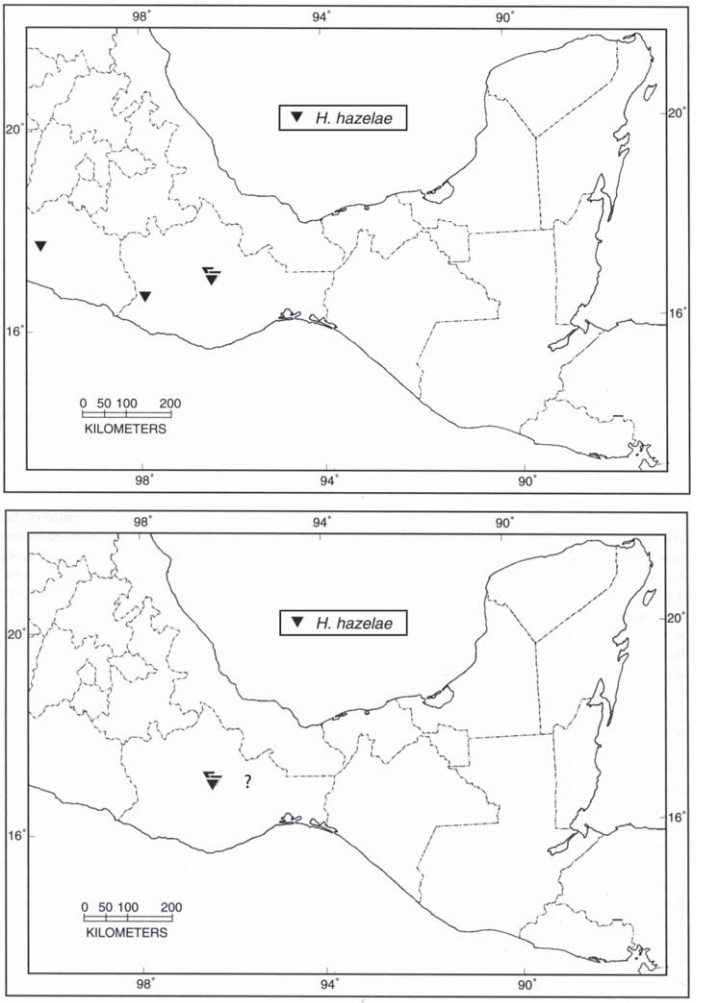

FIG. 1a (top). The distribution of *Plectrohyla hazelae*, as presented by Duellman (2001:fig. 386), showing putative localities for the species in the Sierra Madre del Sur, Sierra Yucuyacua, and the Sierra Aloapaneca or Guerrero and Oaxaca, Mexico. This figure does not indicate the record (KU 13707) from near the town of Tamazulapan, Oaxaca, in the Sierra Mixes; this record was listed by Duellman (2001) but does not appear on this map (see text). This figure has been modified from the original (Duellman, 2001:fig. 386) to exclude locality records of species not relevant to the current paper.

FIG. 1b (bottom). Our current concept of the distribution of *Plectrohyla hazelae*, indicating that it is once known to have once existed only on the slopes of Cerro San Felipe, in the Sierra Aloapaneca of Oaxaca, Mexico. The species was last seen alive in 1975 (see text). The question mark indicates the locality for the specimen (KU 137037) from near Tamazulapan, in the Sierra Mixes of Oaxaca, Mexico, that is here referred to *Plectrohyla* sp. indet.

TABLE 1. Identifications and notes on specimens referred to *Plectrohyla hazelae* by Duellman (2001:1125).

Specimens	Locality	New Identification	Comments
CAS 143106–07	Guerrero: Puerto de Gallo	*Plectrohyla mykter*	Juveniles
MSU (uncatalogued)	Oaxaca: 16 km SE Cuquila	n/a	Specimens lost (see text)
USNM 224499	Oaxaca: 4.7 km W La Cumbre	*Plectrohyla hazelae*	Last known specimen of *P. hazelae;* collected in 1975
KU 13707	Oaxaca: between Tlahuitoltepec and Tamazulapan	*Plectrohyla* sp. indet.	Metamorphic individual; identity uncertain. Unclear if this record was incorrectly mapped by Duellman (2001: fig.386), or whether it was not mapped (see text).

collections of Michigan State University; however, these specimens cannot be located under any taxonomic name (L. Abraczinskas, *in litt.*). Subsequent research indicated that two hylid frogs were collected at that locality by Robert G. Webb on 21 July 1968 (Field Numbers: RGW 4784, 4785; original locality written as "10 mi southwest Cuquila"); squamate specimens collected there at the same time are present in the MSU collection. Webb (*in litt.*) verified the collection of the specimens from his field notes and recalls physically showing them to W. E. Duellman in some informal setting, perhaps at a meeting. Duellman, however, (*in litt.*) has no written record, nor recollection, of the specimens. All other material collected by Webb during that era was deposited at MSU, but our search (www.herpnet.org) and queries to other collection managers, including KU, found no amphibians bearing locality information referencing the tiny village of Cuquila. Evidently, the specimens were never catalogued in a museum and are missing. Based on the lack of voucher specimens, and our own opinion that this is an unlikely locality for a species otherwise known only from the slopes of Cerro San Felipe, we believe this locality record to be in error. An additional specimen (KU 137037) reported by Duellman (2005:1125) from Oaxaca "btw Tlahuitoltepec & Tamazulapan" is also problematic. The specimen is a barely post-metamorphic individual, and thus difficult to identify. However, the presence of nearly complete webbing on the feet (versus about half-webbed in *P. hazelae*) indicates that it is not referable to *P. hazelae;* we here refer it to *Plectrohyla* sp. indet., pending review of other specimens from the region. An additional inconsistency exists in the map presented by Duellman (2001:fig. 386) in that it does not show a locality in the Sierra Mixes, where KU 137037 was collected. It is possible that this locality was confused with another village named Tamazulapan existing in the Sierra Yacuyuna, near the towns of Tlaxiaco and Putla; however, the map shows only one symbol for that region, so it is not clear if that symbol refers to KU 137037 and/or the missing MSU specimens, or was intended to indicate both localities (because, as it turns out, the village of Tamazulapan in this region is near Cuquila). In either case, the symbol should be removed from the distributional map of *P. hazelae* because there is no evidence that the species occurs there. In Fig. 1b, we illustrate our concept of the distribution of this species, which can now be summarized simply as the immediate vicinity of Cerro San Felipe, in the Sierra Aloapaneca of Oaxaca, Mexico. We also note that specimens (TNHC 28598–99; Oaxaca: 13 km NW Ixtlán de Juárez) referred to *P. hazelae* by Duellman (2001:704) do not represent that species and are perhaps referable to *Ecnomiohyla miotympanum.*

Finally, we sadly report that recent intensive amphibian surveys on Cerro San Felipe have uncovered no specimens of *Plectrohyla* (G. Parra-Olea, T. Papenfuss, and D. Wake, *in litt.*). Whereas adults of *Plectrohyla* spp. sometimes can be difficult to locate, the stream dwelling tadpoles are obvious, and present year-round (JRM, personal observation; J. A. Campbell, personal communication; Lips et al., 2004). We estimate this species became extinct sometime probably not very long after 1975—just as proposed by Lips et al. (2004)—when the last known specimen (USNM 224499) was collected on Cerro San Felipe by our colleague Roy W. McDiarmid.

Acknowledgments.— Carl Franklin, Jonathan Campbell, Darrel Frost, Linda Abraczinskas, Robert Webb, William Duellman, Karen Lips, Amanda McDaniel, Jason Brock, David Wake, Ted Papenfuss, and Gabriela Parra-Olea all kindly provided considerable assistance and information for this project. We are grateful to the curators of FMNH, USNM, KU, TNHC, and AMNH for permission to review specimens from those collections.

A Method for Constructing an Adjustable Platform to Obtain Lateral Photographs of Larval Anurans

MATTHEW C. SCHACHT
and
LANCE D. McBRAYER*
Department of Biology, 202 Georgia Avenue
Georgia Southern University, Statesboro, Georgia 30460, USA

** Corresponding author; e-mail: lmcbrayer@georgiasouthern.edu*

Digitally photographing specimens and using computer software to obtain morphological measurements is a commonly used technique in larval anuran research. Lateral photographs of specimens can be used to obtain measures such as snout-vent length, body height, tail length, tail height, tail musculature length, and tail musculature height (Dayton et al. 2005; Lardner 2000; Relyea 2001). However, obtaining quality lateral photographs of larval anurans can be difficult due to their general body plan (a rounded body and laterally compressed tail).

When a specimen is laid on its side in a lateral view, the tail remains flat and in the horizontal plane, but the curvature of the body often causes the specimen to bend so that the body and tail are no longer aligned in the horizontal plane (Figs. 1a and 1b). If the specimen is bent when photographed, measurements of total length or snout-vent length are likely to be underestimates (Fig. 1b). Thus, it is necessary to compensate for the lateral curvature of the body in order to maximize the accuracy of measurements obtained from lateral photographs.

McDiarmid and Altig (1999) describe a modified aquarium apparatus for photographing larval anurans. While this apparatus may be ideal for photographing specimens for voucher or identification purposes, its application in morphological studies may be suboptimal due to its large size, need for clear water to submerse specimens in, and requirement of an electronic flash that is independent of the camera. Because morphological studies often require large sample sizes, decreasing the amount of time it takes to prepare a specimen for photographing is important for efficiency purposes. We describe a simple method for constructing an adjustable platform that enables researchers to consistently and rapidly obtain quality lateral photographs of formalin fixed, or anesthetized, tadpoles. This platform supports specimens in a manner that prevents bending caused by the lateral curvature of the body (Figs. 1c, 1d), and can accommodate variously sized species or broad ontogenetic series of specimens.

Platform construction can be completed in less than 30 minutes with the following materials: two standard microscope slides (3 in. x 1 in.); two hollow tubes, one with a slightly larger diameter than the other; and epoxy glue. The microscope slides act as a platform on which the tail and tip of snout of rest. The hollow tubes are glued beneath the microscope slides and allow the platform to be adjusted. For tubes, we used a drinking straw and the shaft of a disposable ink pen. The smaller diameter tube (i.e., the straw) is cut into two 3-inch pieces and glued parallel to the short edge of the slide approximately one-half inch from each end. The pieces of straw should protrude at least one-half inch from the long edge of the microscope slide. The larger tubes (pen shafts) are then glued to the second microscope slide in the same manner as previously described, with the exception that the circular openings of the shafts should not protrude from underneath the microscope slide (Fig. 2). The microscope slides are aligned and the two pieces of drinking straw (or tube with smaller diameter) are inserted into the pen shafts (tube with larger diameter).

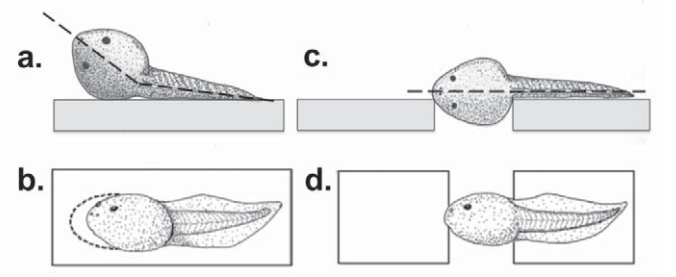

FIG. 1. (a) Side view illustration showing the bending of a larval anuran specimen caused by the lateral curvature of the body. The dashed line is provided to enhance visualization of the degree of bending. (b) Specimen a, viewed from above. The dashed line shows where the outline of the head would be if the specimen's body and tail were aligned in a flat plane. (c) Side view of a specimen supported in a manner that prevents the lateral curvature of the body. (d) Specimen c, when viewed from above.

The larger diameter of the disposable ink pen allows the stage to be quickly and easily manipulated to accommodate specimens of different sizes. A scale bar can be glued to the surface of either microscope slide so that it will be in the field of view with the specimen and in the same plane as the specimen when it is photographed from directly above (Fig. 2). Specimens are positioned on the platform so that only the extreme anterior of the body (snout) is touching the slide on the left, and the tail is supported by the slide

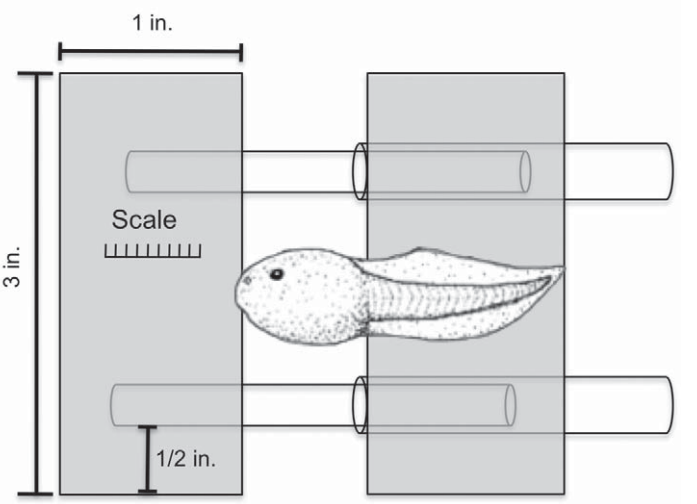

FIG. 2. Larval anuran specimen properly positioned on the completed platform. Selected dimensions of the platform are provided. The finished platform rests on a flat surface and photographs may be obtained by positioning a camera directly above.

on the right (Figs. 1c, 1d, and 2). From the author's experience, the apparatus is easily manipulated and facilitates rapid handling and photographing of specimens.

We have found this apparatus to be both durable and efficient, as it has been used to obtain over 500 photographs of specimens, with an approximate handling time of under 20 seconds for each specimen. Further, this platform is especially useful when photographing smaller species of larval anurans (e.g., *Bufo terrestris*, < 40 mm total length), or very small specimens at early developmental stages. Simple modifications such as adding an additional microscope slide to one side of the platform may be necessary in order to photograph very large specimens (e.g., *Rana catesbeiana*) or late developmental stages of large species.

Acknowledgments.—We thank Steve Williams, Tim Gowan, Dana Nayduch, and three reviewers for their valuable critiques of earlier versions of this manuscript. The research associated with this manuscript was approved by the Georgia Southern University IACUC, and funded in part by grants from Georgia Southern University.

Understanding the potential biases associated with a sampling method are necessary before undertaking a study of the ecology of any organism (Dodd 2003; Gunzburger 2007). Trapping is an effective way to determine whether a species is present in a certain habitat, and many forms of passive traps for aquatic salamanders have been developed, including minnow traps and other funnel traps, leaf litterbags, and box traps (Dodd 2003; Heyer et al. 1994). Baiting passive traps to attract organisms may increase the number of animals captured, but it may also introduce sampling bias to a study (Sorensen 2003). Baiting might attract more animals to an area than normally would be found there, which could lead to an overestimate of abundance. Another bias could be a potential change in behavior or survival of the target species due to predators that are also attracted to the bait. There also could be differences among target species in their food preferences and response to different types of bait.

The Greater Siren (*Siren lacertina*) and Two-toed Amphiuma (*Amphiuma means*) are large aquatic salamanders that are relatively poorly studied, perhaps because of their cryptic behavior and the perceived difficulty in sampling their habitats. These species co-occur throughout most of their geographic ranges in the Southeastern Coastal Plain of the United States (Petranka 1998), though inter-specific interactions may affect microhabitat occupancy (Snodgrass et al. 1999). Both salamanders are primarily nocturnal, with daylight activities restricted to either dense aquatic vegetation or hiding in burrows in the substrate (Duellman and Schwartz 1958; Freeman 1958; Knepton 1954). Limited data on their movement patterns suggest these salamanders have relatively small home ranges (Sorensen 2004) with occasional short dispersal across land during heavy rain or flooding (Aresco 2002; Carr 1940; Gibbons and Semlitsch 1991).

The diet of these salamanders may have significant influence on the effectiveness of baiting to attract these species to traps. Although there is considerable overlap in the diet of these species, diet studies suggest Amphiumas are more carnivorous than Sirens. This is supported by stable isotope analysis that placed Amphiumas at a higher trophic position than Sirens in a North Florida lake (Aresco and James 2005). Dietary analyses of Amphiumas, based on foraging habits or stomach contents, have shown they are entirely carnivorous, feeding on insects (both aquatic and terrestrial), many types of amphibians (including conspecifics), reptiles, fish, crayfish, mollusks, and spiders (Chaney 1951; Hamilton 1950; Hargitt 1892; Lee 1969; Machovina 1994). In contrast, plant material has often been found in dietary analyses of Sirens (Davis and Knapp 1953; Dunn 1924), although other studies have shown Sirens ingest invertebrates, especially mollusks, and fish along with vegetation (Burch and Wood 1955; Hanlin 1978; Moler 1994). *Siren lacertina* are able to effectively digest plant material, as the gastrointestinal structure of *S. lacertina* is similar to other vertebrates that use fermentative digestion (Pryor et al. 2006).

Differential movement patterns also may affect the capture of these salamanders, with more mobile species having a greater likelihood of encountering a passive trap than sedentary species. Unfortunately, there have been few studies examining movements of these species within habitats. A study conducted in Missouri of *Siren intermedia* noted most movements were > 10 m (75% of the population), with a mean home range of 94.8 m^2 (Frese et al. 2003). Another study found > 77% of the movements of *S. intermedia* in Texas were < 6 m (Gehlbach and Kennedy 1978).

The objective of this study was to evaluate the effect of baiting traps on capturing *Siren* spp. and *Amphiuma means*. A previous study (Sorensen 2004) found that baiting did not influence the capture rates of *Siren* spp. and *A. means* in crayfish traps, but we

believe that study may have been biased by the close proximity (one meter apart) of baited and unbaited traps. Chemical cues from the bait (canned sardines in oil) may have pervaded the entire trapping area (Sorensen 2004). The difference in trap spacing used for this study should eliminate the biases that may have been involved in the previous study.

Materials and Methods.—This study was conducted during two trapping intervals in June–July 2006 at Lake Suggs, a 34 ha dark-water lake at the Ordway Swisher Biological Station in Putnam County, Florida (USA). Our study used a blocked design, with four blocks of 10 traps for a total of 40 traps. Traps were deployed along a single transect with one trap every five meters (195 m long transect). The transect was set ca. 3–4 m from the shoreline in dense submergent aquatic vegetation (*Limnobium spongia*, *Pontedaria cordata*, and *Hydrocotyle* sp.). Two blocks (one half of the transect line) were baited in the first trapping interval (5–9 June 2006) and the other two blocks were baited in the second trapping interval (3–7 July 2006). The remaining two blocks in each trapping interval did not have bait added to them. Baiting an entire block of traps and separating each block by 5 m allowed us to prevent contamination of unbaited traps by chemical cues from nearby baited traps. Because it is unlikely salamanders are distributed equally along the length of the transect, our design allowed us to evaluate separately the effect of baiting and block location on the number of animals captured.

We used modified crayfish traps (Lee Fisher International, Tampa, Florida) lined with 0.5 mm mesh which were attached to a PVC pipe anchored into the substrate (Johnson and Barichivich 2004). Traps were baited with canned sardines in olive oil; holes were punched in the can and the can was suspended inside the trap with a length of cord. Bait was not replaced daily, but rather one can of bait was left in each baited trap for the entire trap interval. Traps were set for four nights per interval (320 total trap-nights) and checked every morning.

We analyzed capture rates of each salamander species separately because we do not know the actual population size of either species nor the proportion that were captured in the traps, so we cannot evaluate the relative efficacy of the traps across species. Capture data could not be made normal with transformation, so we conducted Kruskal-Wallis one-way ANOVAs for each species with number captured as the dependent variable and presence of bait, sampling interval (June or July), and block as factors.

Results.—A total of 147 individuals (new captures and recaptures) were caught during the two sampling intervals, including 87 *Amphiuma means*, 56 *Siren lacertina*, 3 *S. intermedia*, and 1 small *Siren* sp. that escaped prior to identification. The number of new captures of unmarked individuals was 106, comprised of 52 *A. means*, 50 *S. lacertina*, 3 *S. intermedia*, and 1 unidentified *Siren* sp. Numbers of all *Siren* species were pooled for data analysis. The mean catch per unit effort (CPUE; captures/trap-night) for the two-month duration of this study was 0.27 *A. means*/trap-night and 0.18 *Siren* spp./trap-night. This CPUE was higher than the previous study (0.11 *A. means* /trap-night and 0.10 *Siren* spp./trap-night; Sorensen 2004).

Baited traps captured 72% (N = 106) of the animals whereas unbaited traps captured 28% (N = 41). Several individuals from the two-month sampling period were recaptured more than once, and multiple salamanders were captured in the same trap on several occasions. Multiple salamanders were captured in the same trap on 23 occasions during the two-month sampling period: six traps with multiple *A. means*, three traps with multiple *Siren* spp., and 14 traps with a combination of *A. means* and *Siren* spp. Sorenson (2003) reported multiple captures in the same trap on seven occasions over a 12-month period. The results of the Kruskal-Wallis analyses showed that the effects of block and sampling interval were not significant for either species. Significantly more *Amphiuma* were caught in baited traps relative to unbaited traps (Mann-Whitney $U = 1492$, $p < 0.001$); there was no correlation of capture rates of *Siren* with baiting (Fig. 1).

Discussion.—Baiting of traps did not have the same effect on capture rates of these two species of salamanders. The dietary differences of these species accurately predict their response to bait: The carnivorous *Amphiuma means* is strongly attracted to bait, while the omnivorous *Siren* spp. were apparently not attracted to bait. Although not significant, both this study and Sorensen (2003) demonstrated a trend towards higher capture rates of *S. lacertina* in unbaited traps (Fig. 1).

The high capture rate of *A. means* could be due to the more predaceous behavior of *A. means* or other factors such as the ability of *A. means* to detect and locate bait. *Amphiuma means* can be caught on a trotline baited with dead crayfish (Chaney 1951), suggesting that chemoreception may play a role in locating prey by these salamanders. In contrast, a laboratory experiment suggested that chemical cues do not seem to play a role in prey location by *S. intermedia* (Sullivan et al. 2000).

Although we did not conduct comparisons across species, Willson et al. (2005) noted higher numbers of *Siren* spp. captures (N = 228) in commercial funnel traps compared with *A. means* (N = 14). Baiting was not part of their experiment, but the lack of bait within traps could explain the higher capture rates of *Siren* spp. over *A. means*. If baiting does attract *A. means*, then *Siren* spp. may be avoiding these traps because *S. lacertina* has been documented as a prey item in *A. means* stomach analyses (Machovina 1994).

Our study demonstrates that the decision of whether or not to use baited traps is likely to influence the outcome of trapping efforts for

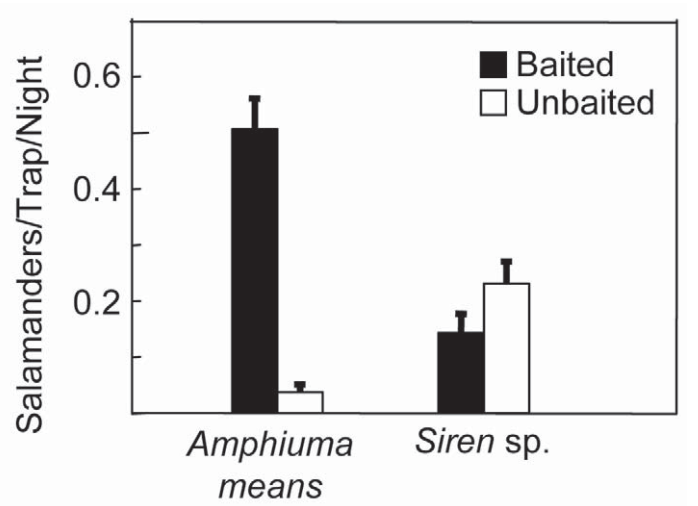

FIG. 1. Mean and standard error of catch per unit effort (number of captures/trap/night) of *Amphiuma means* and *Siren* sp. in 20 baited and 20 unbaited crayfish traps in two four-night sampling intervals.

these species of aquatic salamanders. We suggest that researchers conducting rapid assessment surveys for large aquatic salamanders, in which the response variable is detection or non-detection of a species, should use both baited and unbaited traps to increase the likelihood of trapping both *Siren* spp. and *Amphiuma* spp. if they are present. In contrast, if researchers are more interested in conducting long-term demographic studies, using unbaited traps may result in a more accurate and unbiased reflection of the relative abundance of the two species. We suggest researchers may minimize the likelihood of making critical errors in interpreting population data by conducting even a short-term series of trials designed to understand sampling biases prior to initiating longer-term studies.

Acknowledgments.—We thank S. Coates and M. Sunquist for access to the Ordway Swisher Biological Station under permit OR-05-07. We thank K. Sorensen for advice and access to the previous data collected at this site. C. K. Dodd, Jr., W. Barichivich, and J. Staiger provided comments on earlier drafts of this manuscript. The amphibian chytrid fungus *Batrachochytrium dendrobatidis* (*Bd*) has been identified as an exceptionally devastating amphibian pathogen, capable of acting as both the proximate and ultimate causes of amphibian extinction (Wake and Vredenberg 2008). As described by Skerrat et al. (2007), *Bd* is a highly transmissible pathogen, which has recently been recognized as an invasive species and listed as notifiable by the World Organization for Animal Health (OIE: http://www.oie.int/eng/normes/fcode/en_chapitre_2.4.1.htm#rubrique_batrachochytrium_dendrobatidis). In recent years, significant advances in field and laboratory techniques have enabled scientists to detect *Bd* within amphibian species using non-lethal methods (Annis et al. 2004, Boyle et al. 2004, Hyatt et al. 2007) which has increased our ability to test amphibians that would otherwise not be testable due to regulatory restrictions on take of endangered species. Detection of *Bd* in extant populations is an important component in assessing the status of a population or species because it reveals an elevated risk for subsequent population declines. Therefore, identifying the distribution of *Bd*-infected amphibians can help guide the investment of resources towards areas in most need of frequent monitoring. However, contemporary *Bd* occurrence does not provide data as to when the pathogen was introduced into a geographic area. Contemporary surveys are often unable to show the length of time between the arrival of *Bd* and the onset of population declines.

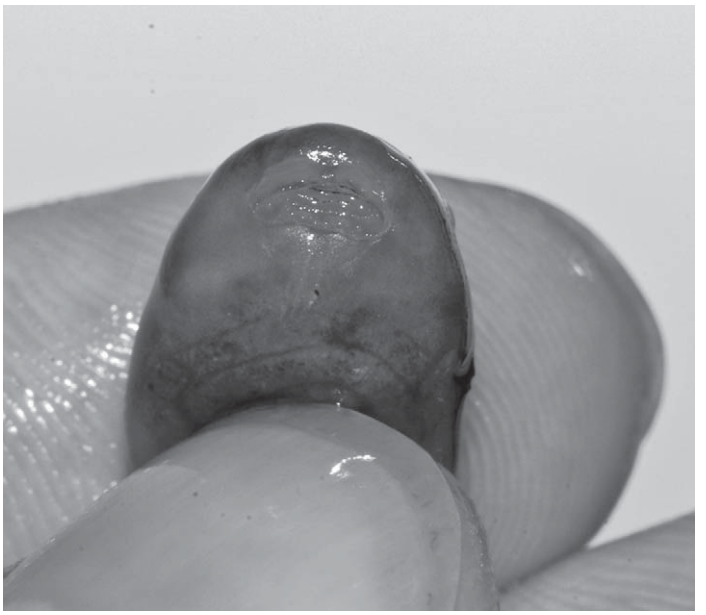

FIG. 1. Ventral anterior surface of the larval *Plectrohyla dasypus* collected in 1996 (USNM 523472) which was examined histologically for *Batrachochytrium dendrobatidis* infection. Specimen displayed gaps in tooth rows and erosion of jaw sheaths.

Developing a timeline of *Bd* introduction in a specific area requires multiple surveys that encompass a timeframe ranging from pre-*Bd* introduction through post-*Bd* arrival. *Bd* was identified only 11 years ago, and by the time it was described and testing techniques for infection were made available, *Bd* had already become widespread (Stuart et al. 2004); thus for many localities, determining the timeline for *Bd* introduction requires retrospective analyses of archived specimens. As we demonstrate in this article, such retrospective studies need not be expansive to produce valuable data regarding the earliest known occurrence of *Bd* in a species or geographic location.

In 2007, we confirmed the presence of *Bd* within Cusuco National Park, Honduras (Kolby et al. 2009). A species of particular concern was *Plectrohyla dasypus*, an amphibian endemic to Cusuco National Park which displayed an alarmingly high prevalence (78%) of *Bd*. This species is listed as Critically Endangered by the IUCN Red List of Threatened Species, in part "… because of a drastic population decline, estimated to be more than 80% over the last ten years, inferred from the apparent disappearance of most of the population (probably due to chytridiomycosis)" (Cruz et al. 2004). Although current and historic observations suggest the involvement of *Bd* in these declines, a cause and effect relationship has not been definitively demonstrated. This is especially relevant for *P. dasypus*, now a candidate for *ex situ* management, as the future of the species is dependent upon an accurate identification of the causative factors driving the impending extinction. Therefore, the answer to the following question carries profound importance: Has *Bd* been present in Cusuco National Park, Honduras for at least 10 years?

Field surveys conducted in 2007 revealed a high incidence of oral defects in *Bd*-infected *P. dasypus* larvae (Kolby et al. 2009), leading us to suspect that oral defects in this species may often be indicative of *Bd* infection. The earliest published record of larval oral defects in this species originated from a series of five larvae (USNM 523472) collected from Cusuco National Park in 1996 (McCranie and Wilson 2002). Morphological examination of this larval series was conducted at the Smithsonian Museum of Natural History on 27 February 2008. Using a 20x hand lens, oral defects were observed in two of the five specimens, which included gaps in tooth rows and erosion of jaw sheaths. We selected one of these two specimens for histological examination to diagnose *Bd* (Fig. 1).

We excised the complete oral disc intact including the underlying soft tissue and stored the samples in 70% ethanol. Tissues

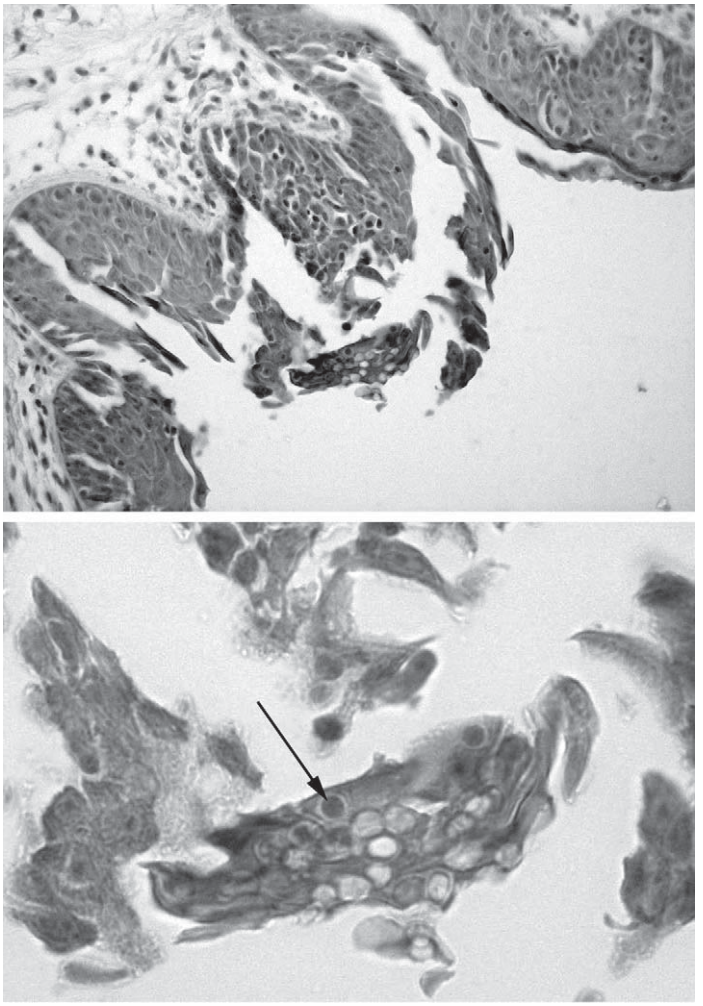

FIG. 2. Top: *Batrachochytrium dendrobatidis* infection in the toothrow of larval *Plectrohyla dasypus* viewed via light microscopy at 200×. Bottom: *B. dendrobatidis* infection viewed at 400×. Dark staining in some cells indicates bacterial colonization of empty zoosporangia (arrow).

were paraffin-embedded, serial-sectioned in 4-µm increments and haematoxylin-eosin (H&E) stained for examination under light microscopy. The specimen was found to be infected with *Bd* when serial sections were viewed by light microscopy. *Bd* thalli and empty zoosporangia were clearly distinguishable in the toothrows and were characterized by thick cell walls and slight ovoid shape (Fig. 2).

Our examination confirmed the presence of *Bd* in Cusuco National Park, Honduras in 1996, seven years earlier than is currently documented for the country (Puschendorf et al. 2006). Since the population decline of *P. dasypus* is believed to have commenced in approximately 1994 (Cruz et al. 2004), our findings chronologically align the presence of *Bd* with the onset of enigmatic decline. Analysis of samples collected in 2007 (Kolby et al. 2009) revealed a high prevalence of *Bd* and confirmed infection in a recently metamorphosed *P. dasypus* which displayed behavioral symptoms of amphibian chytridiomycosis (lethargy, loss of righting reflex, etc.) immediately preceding death. Integrating our contemporary field survey data with retrospective histological analysis, it now seems reasonable to consider *Bd* as a potential proximate and ultimate factor in the decline of *P. dasypus* over the past decade. Since a multitude of other factors (e.g., global climate change, habitat alteration, and xenobiotics) could similarly precipitate an amphibian population decline, the testing of potential cause-effect relationships related to these variables is crucial in determining whether an *ex situ* conservation management plan will be necessary and feasible to prevent extinction of *P. dasypus*.

Acknowledgments.—We thank R. McDiarmid and the National Museum of Natural History, Smithsonian Institution, for permission to examine the referenced specimens.

In Costa Rica, 34% of known amphibian species are classified as threatened; chytridiomycosis (infection caused by *Batrachochytrium dendrobatidis* (*Bd*)) is listed as a known or possible cause of decline for more than half of these species (Stuart et al. 2004). While *Bd* is known to be associated with extirpations of amphibian populations at high elevations in Latin America (Lips et al. 2006), this pathogen also exists at low elevations (Puschendorf et al. 2006), where its effects on amphibian populations are unclear.

The Osa Peninsula, on the southern Pacific coast of Costa Rica, contains a mixture of lowland tropical forest and cattle pastures (Sanchez-Azofeifa et al. 2002). Annual precipitation in this area reaches 5500 mm per year, with a dry season from December to April and a wet season from May to November (Sanchez-Azofeifa et al. 2002). Mapping of *Bd* outbreaks from northwest to southeast in Latin America indicates that this area may have been exposed between 1988 and 1993 (Lips et al. 2006); however, ecological niche modeling does not predict that the Osa Peninsula includes the fundamental niche of this fungus (Ron 2005). While no rapid declines of frog populations have been documented in the Osa Peninsula, population declines of some species of the genera *Craugastor* and *Allobates* are suspected to have occurred in recent years (M. Sasa, pers. comm.). We tested frogs for *Bd* along three streams in this region to quantify the prevalence of this pathogen and investigate local patterns of infection.

Methods.—We surveyed three streams on the Osa Peninsula between 27 May and 8 June 2006 (Fig. 1). The first stream was Quebrada Aguabuena in the Rincón area on the north side of the peninsula (70 m elev., 1.4 km survey length; 8.7001°N, 83.5234°W), the second was Quebrada Bilingual on a private farm near Piro on the southeastern side of the peninsula (30 m elev., 0.8 km survey length; 8.4292°N, 83.3583°W), and the third was Quebrada Cameronal near the Sirena station in Corcovado National Park, on the south-central side of the peninsula (25 m elev., 0.9 km survey length; 8.4292°N, 83.3583°W). Over 1000 researchers and students visited the Rincón area between 1962 and 1973 because the Osa (Rincon) Field Station was located there (Christen 1995), and the Sirena station currently receives a large number of international visitors per year. Piro has had very few visitors outside of local families. Due to heavy rain and low activity of frogs on the stream at Sirena, we supplemented our sample by surveying higher ground and collected samples from six frogs along the stream at a later date (21–22 September 2006).

We sampled each site on several consecutive nights, from just after sundown until frog encounters became less frequent (usually around midnight). We hand captured each frog using fresh, powder-free latex gloves. We swabbed the underside of each frog, including toes, with a wooden-handled swab (Puritan Medical Products, Guilford, Maine, USA) for approximately 20 passes and preserved the swab in salt solution (20% DMSO, 0.25 M EDTA, 100 mM Tris, pH 7.5 and NaCl to saturation; Seutin et al. 1991). These tubes were stored at room temperature until DNA extraction. Locations of captured frogs were recorded with a Garmin GPS 12XT (Garmin Ltd., Olathe, Kansas, USA) or determined using compass and measuring tape from GPS locations.

We extracted DNA from the swabs using a DNeasy Blood & Tissue Kit (Qiagen, Valencia, California, USA), adapting the tissue protocol by heating the AE solution to 55ºC before elution and incubating the sample in the AE solution at 70ºC for five minutes before the final centrifugation. We used an Applied Biosystems 7500 Fast Real-Time PCR System (Applied Biosystems, Foster City, California, USA) to test for the presence of *Bd* using the protocol of Boyle et al. (2004) with the following changes: total reaction volume was 20µl, probe concentration was 125 nM, extracted DNA was not diluted, and one out of the three wells for each sample contained the internal control recommended by Hyatt et al. (2007) to ensure there was no inhibition of the reaction. International quantification standards were obtained from the Australian Animal Health Laboratory (Geelong, Victoria, Australia). Any sample testing positive at fewer than all three wells was rerun. A second test with any positive wells confirmed a positive result, while a second test with no positive wells was regarded as a negative result. A negative control was included in each extraction to confirm that there was no contamination.

We calculated overall prevalence of infected individuals at each site and used binomial probabilities to calculate the upper bound of a 95% confidence interval by finding the highest level of prevalence where we had up to a 5% chance of not detecting the pathogen when no *Bd* was detected at a site. For sites where we detected *Bd*, we determined confidence intervals using the relationship between the *F* distribution and the binomial distribution (Zar 1984). For these calculations, we assumed that our procedure was 100% accurate in detecting infection on a sampled individual. Ecological group was determined using breeding and habitat descriptions from Savage (2002).

Results.—Across the three sites, we sampled 178 individuals and found 9 samples that tested positive for *Bd* (Table 1). Overall prevalence of frogs testing positive for *Bd* was highest at Sirena and lowest at Piro, where we found no infected individuals; however, 95% confidence intervals overlapped for all sites. Frogs testing positive were spread among ecological groups (Table 1). Six of seven frogs testing positive for *Bd* at Rincón were found within 120 m of a dirt road crossing the stream; the remaining individual (*Smilisca sordida*) was found 760 m downstream from the road crossing (Fig. 1).

Discussion.—We found a low level of *Bd* infection (approximately 8% prevalence) at two sites on the Osa Peninsula of Costa

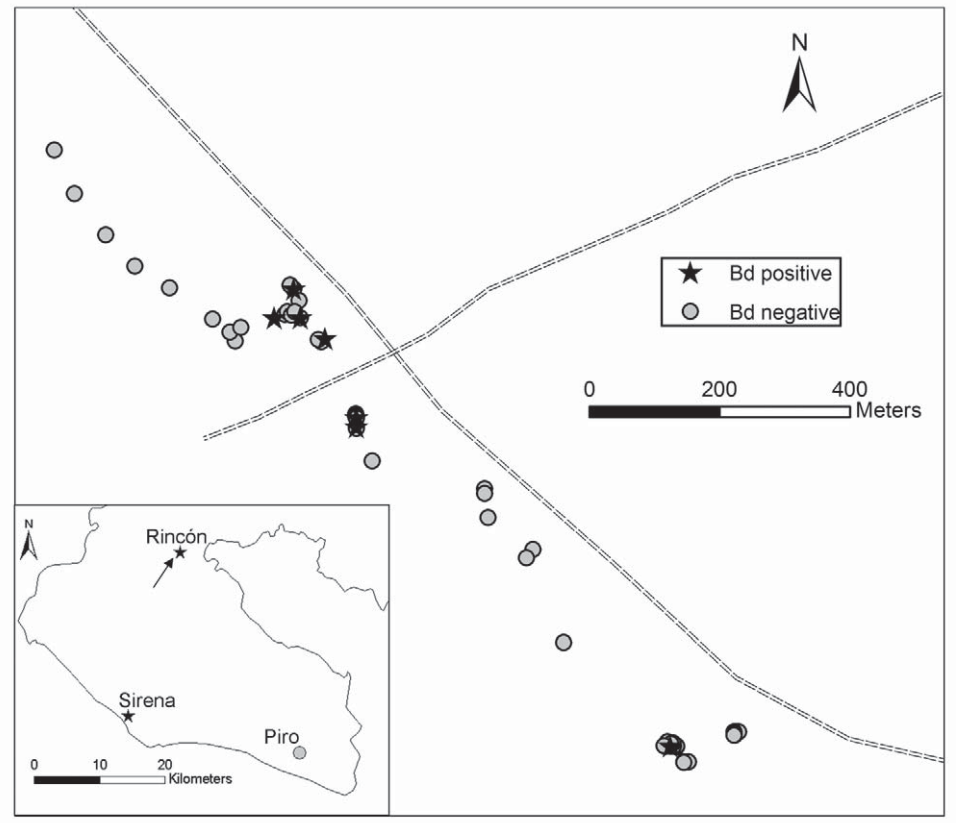

FIG. 1. Location of the three sampling areas on the Osa peninsula, Costa Rica, and *Bd* status of individuals sampled May–September 2006. Large map displays *Bd* status of individual anurans in the Rincón sampling area. Dashed lines indicate dirt roads.

Rica, a lowland region not predicted to contain this pathogen by the niche model of Ron (2005), and we detected no *Bd*-positive individuals at a third site. This estimate of prevalence is similar to that found in live adults by Puschendorf et al. (2006) in an apparently pre-decline amphibian community in Braulio Carrillo National Park, Costa Rica (5.9%) and by Lips et al. (2003) in a declining amphibian community in Las Tablas, Costa Rica (14.3%). Both survey sites on the Osa Peninsula with *Bd*-positive individuals have a history of large numbers of international visitors; the third has received few visitors from outside of the local area. However, our sample size was not large enough to determine if prevalence differed among sites and more data would be required to determine whether frequency of human visitation and *Bd* infection prevalence are correlated.

Within-stream patterns of *Bd* infection may be structured by differences in habitat use and behavior among species (Rowley and Alford 2007; Woodhams et al. 2003). However, the few *Bd*-infected frogs we found were distributed across ecological groups that differed in microhabitat and mode of reproduction. This pattern of infection across species groups is consistent with a survey of Braulio Carrillo National Park, Costa Rica (Puschendorf et al. 2006), and does not follow the pattern found in southeast Queensland, Australia, where frogs breeding in permanent water were more likely to be

TABLE 1. Anurans tested for *Bd* on the Osa Peninsula, Costa Rica, in May, June, and September 2006. For each site (Rincón, Piro, Sirena), number of each species sampled (N) and number testing positive for *Bd* (+) are presented, followed by the quantification of the amount of *Bd* collected in genome equivalents in parentheses. Confidence intervals for prevalence were calculated using the binomial distribution. * Indicates samples collected in September 2006.

infected than frogs breeding in ephemeral or terrestrial habitats (Kriger and Hero 2007).

Along the Rincón stream, we found most infected individuals near a dirt road crossing, with the exception of one *S. sordida* individual found further downstream. While this concentration of infected frogs may be located near the road for unrelated reasons, the pattern could indicate that a reservoir for this pathogen is located outside of the stream and stream frogs are potentially exposed through the movement of vehicles or animals traveling along the road.

Acknowledgments. –We thank D. Bellanero, J. Manning, and D. Matlaga for help in the field and J. Kerby, C. Richards, C. Anderson, J. Adams, and T. Edwards for their help with developing lab protocols. J. Evans, M. Murphy, and two reviewers provided helpful comments on an earlier draft of this manuscript. Funding was provided by NSF-IGERT grant no. 0114304 for C.S.G. and by an EPA fellowship and a Kushlan/Frohring grant from the University of Miami to T.J.H. Field protocols were approved by the University of Idaho (ACUC Protocol 2004-42) and MINAE in Costa Rica (INV-ACOSA—005-06).

Soon after the discovery of the amphibian disease chytridiomycosis, caused by the pathogenic fungus *Batrachochytrium dendrobatidis* (*Bd*, Longcore et al. 1999), it became apparent that *Bd* was a major threat to amphibians resulting in mass die-offs and population declines throughout the world (Berger et al. 1998; Blaustein and Keisecker 2002; Daszak et al. 2003; McCallum 2005; Rachowicz et al. 2006). Evidence suggests that *Bd* infected amphibian populations in Central America as early as the 1980s (Pounds et al. 1997). Work done in Central America has implicated that a wave of *Bd* has moved through the montane regions of Central America and was associated with major declines in amphibian populations and species richness (Lips et al. 2006; Puschendorf et al. 2006). However, in some cases, *Bd* also may occur in amphibian communities with little or no effect on populations (Berger et al. 1998; Brem and Lips 2008; Garner et al. 2006).

We sampled amphibians for the presence of *Bd* in the Kèköldi Indigenous Reserve in the lower elevations of the Talamanca region, Costa Rica, to determine *Bd* infection rates in an area not previously surveyed. Also, we attempted to determine which species might be at greatest risk from *Bd*. Although our study site had not been sampled prior to this study, *Bd* likely reached this region in the early 1990s (see Lips et al. 2006).

We sampled anurans for *Bd* from 6 to 17 January 2008 in the 3538-ha Kèköldi Indigenous Reserve, located in southeastern Costa Rica near Hone Creek in Limon Province (Fig. 1). The habitat in the reserve is mostly secondary forest, underplanted with cacao trees; however some primary lowland tropical rainforest occurs at higher elevations in the reserve. The climate at Kèköldi is hot and

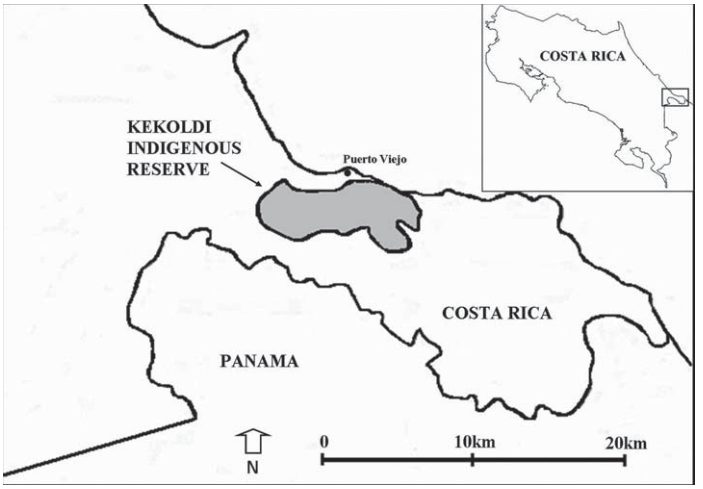

FIG. 1. Study site location, Kèköldi Indigenous Reserve, Costa Rica, where 20 frog species were examined for the amphibian chytrid fungus, *Batrachochytrium dendrobatidis*.

humid year-round, with an annual mean temperature of 26ºC and average rainfall of approximately 2500 mm per year.

We searched for adult frogs along the trails and streams in the reserve and captured them by hand. Each individual was handled with a new pair of sterile nitrile gloves. We sampled for *Bd* by rubbing a sterile cotton swab on the dorsum, ventral surfaces and feet of each frog for approximately 30 sec, then the animal was released. The swab was then immediately placed in a sterile microcentrifuge tube containing 1 ml of 70% ethanol and later sent to Pisces Molecular Lab (Boulder, Colorado, USA) for PCR analyses. Global positioning coordinates and elevation were taken at each capture site using a Garmin® GPS unit.

During 12 days of sampling at Kèköldi, no sick or dead frogs were observed. We sampled 126 adult frogs of 20 different species, from 10 different Families. Of these 20 species, only 8 tested positive for *Bd*. Ten of the 126 individuals tested positive for an overall detection rate of 7.9% for the anuran community. Too few individuals were sampled to determine *Bd* prevalence per species. Only one species, *Craugastor crassidigitus*, had more than one individual (3 of 12) test positive for *Bd* (Table 1). Anurans were sampled at elevations ranging from 29 to 150 m. We had too few positive samples to test for effects of elevation on *Bd* detection rates.

Numerous studies have documented the presence of *Bd* in Central America (Brem and Lips 2008; Lips 1998; Lips et al. 2003; Picco and Collins 2007; Puschendorf et al. 2006). Puschendorf et al. (2006) demonstrated through histological examination of museum specimens that the fungus was present in Braulio Carrillo National Park, Costa Rica, by 1986 at almost all elevations sampled. Declining species richness in amphibian communities along a north-to-south transect in Central America has been linked to *Bd* (Lips et al. 2006). According to the timeline in Lips et al. (2006) tracking the epidemic wave of *Bd* in Costa Rica, the fungus probably reached the Kèköldi Reserve in the early to mid 1990s.

Since *Bd* likely moved through Kèköldi 15 to 20 years prior to this study, it is possible that an initial epizootic event took place resulting in declines in amphibian species richness and abundance followed by a rebound to an enzootic state (Brem and Lips 2008). It is also possible that the fungus never reached an epizootic state in the low elevation Kèköldi Reserve because the warm air temperatures are less than optimal for *Bd* growth and infection of amphibians (Kriger and Hero 2006; Longcore et al. 1999; Retallick et al. 2004). Evidence for enzootic *Bd* includes the relative low incidence of detection in PCR samples and the fact that no sick or dead frogs were encountered. Frogs appeared to be very abundant in the reserve; however follow-up population and *Bd* sampling is needed to confirm whether the *Bd* is currently epizootic or enzootic.

TABLE 1. List of anuran species tested for the presence of *Batrachochytrium dendrobatidis* (*Bd*) within Kèköldi Indigenous Reserve, Costa Rica.

Family	Species	No. animals infected / examined
Aromobatidae	*Allobates talamancae*	0/2
Bufonidae	*Incilius coniferus*	0/1
	Rhinella marinus	0/1
Centrolenidae	*Hyalinobatrachyum valerioi*	0/5
Craugastoridae	*Craugastor bransfordii*	1/13
	Craugastor crassidigitus	3/12
	Craugastor gollmeri	0/1
	Craugastor megacephalus	0/12
	Craugastor noblei	1/2
	Craugastor sp.	0/3
Dendrobatidae	*Dendrobates auratus*	1/9
	Oophaga pumilio	1/16
	Phyllobates lugubris	1/4
	Silverstoneia flotator	0/15
Eleutherodactylidae	*Diasporus diastema*	1/16
Hylidae	*Agalychnis callidryas*	0/1
	Smilisca phaeota	0/1
	Smilisca sordida	1/3
Leptodactylidae	*Leptodactylus savagei*	0/6
Ranidae	*Lithobates warszewitschii*	0/2
Strabomantidae	*Pristimantis cerasinus*	0/1

Detecting *Batrachochytrium dendrobatidis* in the Wild When Amphibians Are Absent

JOEL G. WIXSON
and
KEVIN B. ROGERS*
Aquatic Research Group, Colorado Division of Wildlife
P.O. Box 775777, Steamboat Springs, Colorado 80477, USA

**Corresponding author; e-mail: kevin.rogers@state.co.us*

Once common in the southern Rocky Mountains of North America, sharp declines in Boreal Toad (*Anaxyrus boreas boreas*) populations precipitated their listing as a state endangered species in Colorado, USA (Loeffler 2001) and consideration for listing under the Endangered Species Act (U.S. Fish and Wildlife Service 2005). The amphibian chytrid fungus (*Batrachochytrium dendrobatidis*, hereafter *Bd*) has been implicated in these declines (Livo 2000; Muths et al. 2003; Scherer et al. 2005). Interest in reintroducing *A. b. boreas* into historical habitats (Loeffler 2001) has spurred the need to develop a test for the presence of *Bd*. Reintroduction efforts are time consuming and costly, and their success may hinge on the occurrence of *Bd* at a potential site. As such, it is imperative that disease status be considered when evaluating potential reintroduction efforts.

Currently our ability to detect *Bd* at a site relies on resident amphibians being present, yet they are not at many promising potential reintroduction locations. Since *Bd* can persist at a location even in the absence of amphibian species (Longcore et al. 1999; Rowley et al. 2007; Speare et al. 2001), we suspect that amphibians may not be the only host, and that infection can be maintained through other alternate hosts or environmental reservoirs. We hope that by testing these non-amphibian sources, the *Bd* status at potential reintroduction sites can be evaluated. Rowley et al. (2007) did not detect *Bd* in retreat sites of rain forest stream frogs, while Lips et al. (2006) did find *Bd* DNA on stream boulders but not in filtered water samples. Others have detected *Bd* in filtered water samples (Kirshtein et al. 2007; Walker et al. 2007), but their approaches do not always perform well in waters carrying high organic loads that rapidly clog filters (Cossel and Lindquist 2009) or cause PCR inhibition (Kirshtein et al. 2007). Our initial efforts toward finding alternative *Bd* hosts focused on insects, because they are readily available and chytrid fungi can degrade chitin, a component of aquatic insect exoskeletons (Johnson and Speare 2003; Powell 1993). These early surveys were unable to confirm the presence of *Bd* in samples of Dytiscidae, Coenagrionidae, Hydrophilidae, or Notonectidae from two ponds known to harbor the fungus (Rogers et al. 2004). Samples of Corixidae, algae, snails, and clams taken from a third pond with infected Boreal Chorus Frogs (*Pseudacris maculata*) were also negative for *Bd* DNA (Rogers and Wood 2005). In an effort to establish a more rigorous examination of potential alternate hosts, we initiated a study to explore the feasibility of using sentinel cages and fish following reports that *Bd* could be found on the scales of Fathead Minnows (*Pimephales promelas*) that were exposed to *Bd* in the laboratory (R. Retallick, pers. comm., GHD, Australia). Feathers and keratin were included

in this field study as well when others demonstrated the ability to culture *Bd* on sterile duck feathers (Johnson and Speare 2005) or 1% keratin agar (Piotrowski 2004) *in vitro*.

Methods.—Sentinel experiments were conducted in both a mid-elevation site in the town of Steamboat Springs, Colorado, and a high elevation site on the Grand Mesa, Colorado after the spring thaw in 2005 when prevalence of *Bd* infection was greatest (K. Rogers, unpubl. data). This occurred in May for the low elevation site in Steamboat Springs, and in July for the high elevation sites on the Grand Mesa. *Bd* presence at both sites was confirmed by swabbing resident *P. maculata* following Livo (2004). DNA was extracted from the samples using a standard spin column protocol. All sample DNA preparations were assayed for the presence of the *Bd* ribosomal RNA Intervening Transcribed Sequence (ITS) region by 45 cycle single-round PCR amplification (Annis et al. 2004) that was modified for greater specificity and sensitivity at Pisces Molecular, Boulder, Colorado.

Cages (0.125 m^3) were constructed of 4 × 4 cm pine boards and 3 mm mesh to house sentinel animals. Cages were deployed in water less than 60 cm deep, and secured to the bottom with metal stakes. A protective hardware cloth (25 mm mesh) was attached to the outside of each cage to protect them from predators. Sentinel fish were sampled for *Bd* at 1, 3, 7, and 14 days following introduction to the cages, and mortalities were noted. Fish were swabbed on their right flanks one day after exposure. After 3, 7 and 14 days of exposure, 10 fish of each species from each pen were euthanized with MS-222, then swabbed, scraped, and fin clipped. A cotton swab (Puritan cotton-tipped applicators, VWR International, West Chester, Pennsylvania), was stroked 20 times unidirectionally across the left flank of each sentinel fish, then preserved in 70% ethanol (Livo et al. 2004) for subsequent PCR screening. The skin scrapes followed a similar protocol but used a sharpened wooden dowel (Livo 2004). Paired and caudal fins were removed and preserved in 70% ethanol.

In addition to sampling sentinel fish, six mallard (*Anas platyrhynchos*) flank feathers were taped together at the stalk and suspended in the surface film with a string attached to the outside of the cage. A feather was collected on each sampling day by clipping the exposed end of the feather and placing the complete piece in a 2-mL microcentrifuge tube containing 70% ethanol, then processed with the same PCR procedure.

The first study was conducted in a small temporary spring-flooded pond (Trafalger Pond) next to the Yampa River within the city limits of Steamboats Springs, Colorado (2051 m elev.; 40.47445°N, 106.83017°W). Skin swabs from 20 resident adult *P. maculata* collected during the breeding season suggest this pond has harbored *Bd* since at least 2004 (30% prevalence, K. Rogers, unpubl. data). Thirty Rainbow Trout (*Oncorhynchus mykiss*), 30 *P. promelas*, and 30 Goldfish (*Carassius auratus*) were used as sentinel fish in each of four cages spread throughout the pond, in addition to six Mallard flank feathers suspended outside of each cage.

The second study was conducted in the Kannah Creek drainage on the Grand Mesa near Grand Junction, Colorado (3268 m elev.; 39.04420°N, 108.02992°W). Dozens of small ponds in this drainage are home to robust populations of *P. maculata*. Ponds with perennial water also support Tiger Salamanders (*Ambystoma tigrinum*). *Bd* was first detected in this drainage in 2003 in *P. maculata* collected from a 1.0 ha pond (Pond 4) used in this study (Rogers and Banulis 2004). One cage with 30 *P. promelas* was deployed in each of two additional 0.5 ha ponds, hereafter referred to as Lands End and Cow Camp. Pond 4 received two cages, each with 30 *P. promelas*. Six Mallard flank feathers were installed outside of each of the four cages. In addition, we explored baiting *Bd* with pure keratin (VWR International, West Chester, Pennsylvania). Keratin tea bags were constructed from paper coffee filters, cut in half and sewed together. Five bags were fastened to each cage with 3 g of keratin per bag. A bag was removed from each cage on every sampling occasion, and a portion of the contents preserved in 70% ethanol. Skin swabs from 20 adult *P. maculata* were collected from each of these three ponds the day after this 14-day experiment to evaluate the prevalence of *Bd* in 2005.

Results.—In an effort to reduce assay costs in the first study, only the feathers collected at 1, 3, 7, and 14 days following exposure along with fish skin swabs collected one day following exposure on *O. mykiss* and three days following exposure on *P. promelas* and *C. auratus* were submitted for analysis. None of these 16 feather samples or 120 fish samples suggested that *Bd* was present. Because the ability to use sentinel organisms at this site did not appear promising and processing samples was costly, the remaining samples were archived.

In the second study, despite a substantial number of *Bd*-positive samples from the *P. maculata* collected at the end of our experiment (prevalence of *Bd* ranging from 25–30% in all three ponds), only six of 350 fish swab, scrape, and fin samples were *Bd* positive. These included five swabs collected one day after exposure on *P. promelas* in Cow Camp and a single swab from Lands End, also collected one day after exposure that returned a very weak positive signal. None of the fish swabs, scrapes, or fin clips collected 3, 7, or 14 days after exposure yielded positive results. Feathers and raw keratin were equally ineffective, as all 32 samples failed to register any evidence of *Bd* over the course of the experiment.

Discussion.—Caged fish, feathers, and keratin were ineffective at sampling *Bd* in ponds known to have amphibians with the disease. Although swabbing the flanks of *P. promelas* exposed for one day in a *Bd*-positive environment yielded Bd-positive results, fish sampling was clearly much less sensitive than sampling *P. maculata* in the same environment. The fact that the majority of the positive results came from the single cage at Cow Camp, and that positives were found after only one day of exposure but not after a week or two weeks makes the use of *P. promelas* as sentinel organisms problematic. Rather than *Bd* actually infecting the host, this suggests that the cage was fortuitously deployed in an area with *Bd* zoospores, and that they simply adhered to the fish when sampled on that first day. Chytrid spores have a short-lived free-swimming stage that only lasts about 24 hrs before encysting (Piotrowski et al. 2004). Even with this 24 hr active period the spore can only swim 2 cm (Piotrowski et al. 2004). Thus we may have simply been lucky in our placement of the Cow Camp cage in particular. There does not appear to be any particular affinity by the zoospores toward *P. promelas*, as subsequent samples revealed no indication of *Bd* presence. Given the inconsistent nature of the results, it is doubtful that using sentinel *P. promelas* would be a viable approach for screening potential amphibian reintroduction sites for the presence of the fungus. Although sentinel fish have been used to test for pathogens like whirling disease (Koel et al.

2006; Thompson et al. 1999), the construction and deployment of cages remains labor intensive, particularly in sites that are difficult to access. This is an additional consideration, given the apparently low sensitivity of *P. promelas* as a sentinel to detect *Bd*.

Because the majority of positive samples came from the same cage on the same day, contamination of the samples is a concern. The frog samples used to confirm the presence of the fungus were collected following the experiment, and stored in a different location making them an unlikely source of contamination. Using latex gloves between samples, and sterilizing equipment with an open flame further minimized contamination risk. Contamination occurring in the original source stock of *P. promelas* was also ruled out, as most positive signals came from a single cage, and only early in the study. Samples collected after 3, 7, and 14 days were all *Bd*-negative.

Given that others have been successful growing chytrid fungi on a 1% keratin agar (Piotrowski et al. 2004) or on feathers (Johnson and Speare 2005) *in vitro*, we were surprised that none of the keratin or feather samples yielded a positive PCR result. It was suggested that perhaps the *Bd* fungus did not colonize the interior of the keratin bags, but rather just the outside, which was not sampled. Subsequent tests using agar-impregnated swabs rolled in raw keratin however also failed to bait in *Bd* following three days of exposure (K. Rogers, unpubl. data).

If *Bd* has a patchy distribution in a pond environment, it would be difficult to sample with fixed organisms or objects. A more effective approach would be to release amphibians targeted for a reintroduction effort, then subsequently collecting survivors the following year to sample for *Bd*. Using a non-tethered organism allows the target to move through the environment as it would following a repatriation effort, encountering pathogens along the way. Repatriation efforts require the ability to produce large numbers of offspring for subsequent release; a portion of this captive production could be used to assay potential field sites for *Bd*. If a captive broodstock is not available, fertilized eggs could be secured from the wild, washed to minimize risk of *Bd* transfer, then raised to the larval stage for release (Rogers and Banulis 2004). This approach requires that target amphibians be produced during pilot studies prior to implementing full repatriation efforts to determine the suitability of potential translocation sites.

Acknowledgments.—Our gratitude is extended to C. Slubowski who shepherded the sentinel cages on the Grand Mesa and helped collect samples. F. B. Wright III is thanked for assisting with sample collection and providing many helpful ideas. We also appreciate the time of G. and J. Wixson who supplied the necessary tools and advice in building the cages. Substantial improvements to the manuscript were provided by D. Olson, J. Rowley, and an anonymous reviewer. All applicable institutional animal care guidelines were followed during the implementation of this project.

Ranaviruses are a group of pathogens belonging to the genus *Ranavirus* (Family Iridoviridae) that have been linked to catastrophic die-offs of larval amphibians in North America and elsewhere (Daszak et al. 2003). They also have been identified as the etiologic agent in the mass mortality of adult Common Frogs (*Rana temporaria*) and Common Toads (*Bufo bufo*) in the United Kingdom (Cunningham et al. 1996; 2007a,b). In the United States, ranaviruses are responsible for the majority of disease-related mortality events in amphibians (Green et al. 2002; Muths et al. 2006). There is evidence that ranaviruses may be an emerging infectious disease (Storfer et al. 2007), possibly due to novel strain introduction (Picco and Collins 2008) or increased occurrence of anthropogenic stressors on the landscape (Forson and Storfer 2006; Gray et al. 2007). Recognizing the potential threat of ranaviruses to global amphibian biodiversity, the World Organization for Animal Health (OIE) recently listed this pathogen as a notifiable disease, requiring proof of *Ranavirus*-negative results before commercial shipment of amphibians (OIE 2008). The OIE identifies field surveillance as a critical component of risk assessment for ranaviruses (OIE 2008). Although surveillance for the amphibian pathogen *Batrachochytrium dendrobatidis* has become widespread (e.g., Chatfield et al. 2009; Rothermel et al. 2008), testing amphibians for *Ranavirus* occurs less frequently.

The Southern Appalachian Mountain Range of North America represents a global hotspot for salamander biodiversity (Dodd 2004; Petranka 1998). In particular, lungless salamanders (Family Plethodontidae) occur in high abundance and biomass (Peterman et al. 2008; Petranka and Murray 2001) and are important components of the ecosystem (Davic and Welsh 2004). Known die-offs of Eastern Newts (*Notophthalmus viridescens*), Spotted Salamanders (*Ambystoma maculatum*), Pickerel Frogs (*Lithobates palustris*), and Wood Frogs (*L. sylvaticus*) occurred in the Southern Appalachian Mountains due to ranaviruses in 1999 and 2001 (Converse and Green 2005; Green et al. 2002). Despite these mortality events, surveillance for *Ranavirus* in Southern Appalachian amphibians has been nonexistent. Our goal was to test for the presence of *Ranavirus* in lungless salamander communities located in the Southern Appalachian Mountains. We tested for *Ranavirus* in salamander communities at three sites that differed in elevation and report prevalence by species and for each site.

Methods.—We captured adult lungless salamanders for *Ranavirus* testing on 21 April 2007 at three locations in the Great Smoky Mountains National Park, Tennessee: 1) Ash Hopper Branch (456 m elev.; 35.6836°N, 83.5375°W); 2) Chimney Tops Seeps (831 m elev.; 35.6367°N, 83.4928°W); and 3) Indian Gap Seeps (1537 m elev.; 35.61°N, 83.45°W). At all sites, we searched 1 h for salamanders in streams, seeps, and under terrestrial ground cover items (e.g., logs, rocks). We placed captured salamanders in individual 1-L plastic containers and processed up to 10 individuals per species per site. We swabbed the oral cavity and the cloaca twice each. We wore disposable gloves and changed them between animals to minimize the likelihood of cross contamination among samples. We put each swab in separate microcentrifuge tubes, placed the tubes on dry ice, and froze the swabs at -70°C within 10 h of collection. We swabbed 21, 21, and 27 salamanders at Ash Hopper Branch, Chimney Tops, and Indian Gap sites, respectively. All salamanders were released at their approximate capture location within 1 h of capture, and containers, footwear, and equipment were disinfected with 2% Nolvasan® prior to moving between sites (Bryan et al. 2009). We shipped frozen swabs overnight on dry ice to the University of Georgia Veterinary Diagnostic and Investigational Laboratory for *Ranavirus* testing.

We used conventional polymerase chain reaction (PCR) to test for the occurrence of *Ranavirus*. We extracted genomic DNA from swabs using a QIAamp DNA Mini Kit (Qiagen Inc., Valencia, California). A heminested PCR targeting a 500-bp region of the major capsid protein (MCP) gene was used following the protocol by Kattenbelt et al. (2000). The PCR products were resolved by gel electrophoresis for determination of *Ranavirus* occurrence. We randomly chose one sample per species with a distinct PCR-positive band, cut the band from the gel, and submitted the isolated product to SeqWright DNA Technology Services, Houston, Texas, for automated sequencing in the forward and reverse directions. We then performed a GenBank BLAST search (http://www.ncbi.nlm.nih.gov/Genbank.html) on the sequences to verify that positive PCR results were *Ranavirus*. Additionally, real-time quantitative PCR (qPCR) was performed following the procedure by Picco et al. (2007) on samples used for sequencing to further support our findings.

We summarized the positive test results for each species, and tallied *Ranavirus* prevalence among species for each sampling

TABLE 1. Prevalence of *Ranavirus* detected from oral and cloacal swabs using PCR for 10 species of adult lungless salamander, Plethodontidae, in the Great Smoky Mountains National Park, Tennessee, USA, April 2007.

Species	No. Infected/ Tested	Prevalence	Accession Number[1]
Desmognathus conanti	13/14	0.93	GQ326559
D. imitator	11/13	0.85	GQ326560
D. monticola	1/1	1.0	GQ326561
D. ocoee	2/2	1.0	GQ326562
D. quadramaculatus	7/8	0.88	GQ326563
D. santeetlah	11/13	0.85	GQ326564
D. wrighti	1/2	0.5	NS
Eurycea wilderae	8/12	0.67	GQ326565
Gyrinophilus porphyriticus	1/2	0.5	GQ326566
Plethodon jordani	1/2	0.5	NS
Total	56/69	0.81	

[1]GenBank accession number of the DNA sequence used for *Ranavirus* determination; NS = not sequenced because insufficient genomic DNA was amplified for sequencing.

site. We tested for the differences in *Ranavirus* prevalence among sites using logistic analysis and calculated odds-ratio statistics to estimate the likelihood of *Ranavirus* infection for each site (Stokes et al. 2000). All analyses were performed using the SAS® system (SAS Institute, Cary, North Carolina) with $\alpha = 0.05$.

Results.—We captured 10 species of lungless salamanders and all species included individuals that tested positive for *Ranavirus*. The qPCR results matched the conventional PCR results. We were able to sequence the PCR products from eight of the infected species. GenBank BLAST searches on the sequences revealed identities of 94–96% and 97–100% with ATV and FV3, respectively. Overall prevalence was 81% among species and sites (Table 1). *Ranavirus* prevalence differed among sites ($\chi^2 = 7.14$, $P = 0.028$; Fig. 1). Salamanders were 10 and 3 times more likely to be infected at Ash Hopper Branch (odds ratio = 0.1) and Chimney Tops Seeps (odds ratio = 0.3), respectively, compared to the Indian Gap Seeps.

Discussion.—We report the first documentation of *Ranavirus* infecting salamander species in the family Plethodontidae. We documented *Ranavirus* infecting 10 species of lungless salamander at an overall prevalence of 81% among species. The high prevalence of *Ranavirus* in adult lungless salamanders may indicate that they are tolerant of infection. Brunner et al. (2004) reported that postmetamorphic Tiger Salamanders (*Ambystoma tigrinum*) could be asymptomatic carriers of ranaviruses. However, no studies have quantified the pathogenicity of ranaviruses for lungless salamanders or whether virulence differs among developmental stages. Studies with anurans and ambystomatid salamanders suggest that adult stages are less susceptible to *Ranavirus* than larval stages (Collins et al. 2004; Gantress et al. 2003), thus adult amphibians have the greatest likelihood of serving as a *Ranavirus* reservoir. It also is possible that the high *Ranavirus* prevalence was evidence that a die-off was occurring or imminent. Laboratory studies with ranaviruses have shown that infection and mortality rates typically track each other in highly susceptible species (Brunner et al. 2007; Cunningham et al. 2007b). None of the individuals that we swabbed had gross signs of ranaviral disease (e.g., edema, erythema) and dead salamanders were not observed. However, it is important to note that diseased individuals often do not exhibit external signs and die-offs in the wild are rarely observed (Green et al. 2009). Inasmuch as this is the first documentation of ranaviruses infecting lungless salamanders, more research is needed to determine the threat that ranaviruses pose to this diverse group of amphibians.

Although positive results from swab specimens can be an indication of virus infection (Driskell et al. 2009), they also may reflect virions attached to skin surfaces (Green et al. 2009). In a separate controlled study with tadpoles, we determined that PCR test results for *Ranavirus* from swabs have about a 10% false-positive rate for systemic infection when compared with test results from liver tissue (Miller, Gray, and Hoverman, unpubl.

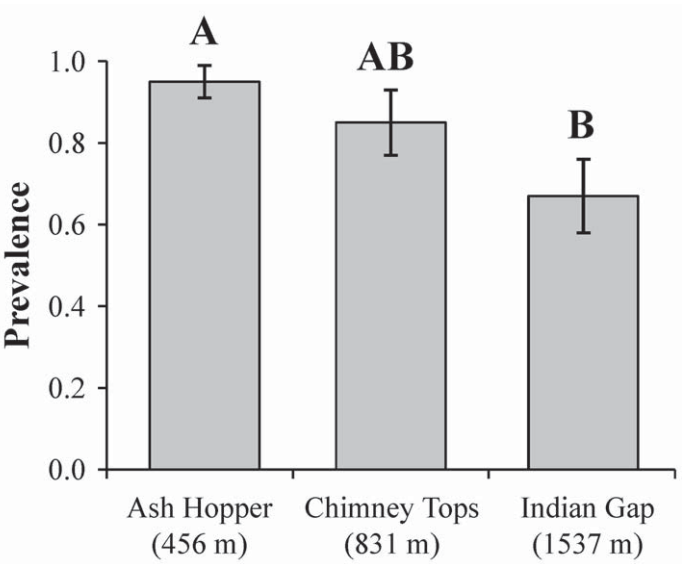

FIG. 1. *Ranavirus* prevalence in lungless salamanders (Plethodontidae) among three sampling locations that differed in elevation, Great Smoky Mountains National Park, Tennessee, USA, April 2007. Bars with unlike letters are different ($P = 0.03$) by Wald's chi-square test; standard error bars calculated as: $\hat{p} \pm \sqrt{\hat{p}(1-\hat{p})/n}$

data). We did not euthanize salamanders in our study so it is unknown if positive swabbed individuals had systemic infections. Nonetheless, given the high prevalence of *Ranavirus* across species, systemic infection of some individuals was possible.

Pathogen prevalence differed among sites, with prevalence increasing with decreasing site elevation. Salamanders at 456 m above sea level were 10 times more likely to be infected with *Ranavirus* than those at 1537 m elev. Greater pathogen prevalence at lower elevation is opposite of the trends reported by previous studies with *Ranavirus* and *Batrachochytrium dendrobatidis* (Brem and Lips 2008; Gahl and Calhoun 2008), which have related differences in infection among elevations to changes in temperature. Inasmuch as stream temperature is relatively constant among elevations in the Southern Appalachian Mountains (Swift and Clinton 1997), more optimal temperature for virus replication or temperature-induced stress probably were not factors responsible for higher prevalence at lower elevation. Higher prevalence at low-elevation sites may reflect greater human access. All sites could be accessed by trails but the sampling location for Ash Hopper Branch was <200 m from the U.S. National Park Service Sugarlands Visitor Center and a campground was <100 m from the Chimney Tops Seeps. In contrast, the Indian Gap seeps were approximately 400 m from a minor parking lot. Greater human access could increase the likelihood of infection by increasing the level of stressors in the environment or by introducing *Ranavirus* virions that are attached to footwear or recreational gear (Green et al. 2009). It also is possible that greater infection at low-elevation sites was a result of watershed position. Most of the salamanders that we collected were in or adjacent to flowing streams. *Ranavirus* virions transmit effectively in water (Harp and Petranka 2006), and they probably remain active outside the host for several months (Langdon 1989). Thus, greater prevalence of *Ranavirus* at lower elevation may be a consequence of cumulative downstream transport of virions and higher contact rates with the pathogen. The possible impacts of factors associated with elevation and human access on exposure frequency and susceptibility of lungless salamanders to ranaviruses need to be explored.

Our results indicate that plethodontid salamanders are suitable hosts for ranaviruses. The pathogenicity of ranaviruses to plethodontid salamanders remains unknown and is a part of ongoing experimental challenges (Gray, Miller, and Hoverman, unpubl. data). Given the high prevalence of *Ranavirus* in Southern Appalachian salamanders, we recommend that surveillance efforts be expanded in this region and perhaps elsewhere. Future efforts should include isolating and molecularly characterizing ranaviruses infecting plethodontid salamanders to determine if they are phylogenetically similar to previous isolates. Given the possible threat of ranaviruses to lungless salamanders, we recommend that researchers take biosecurity precautions to reduce the likelihood of transporting *Ranavirus* virions among watersheds. Bryan et al. (2009) reported that 1% Nolvasan®, 1% Virkon S®, and 3% bleach were effective at inactivating *Ranavirus* after 1 min contact duration. Mud and debris should be removed from footwear and gear prior to applying disinfectant (Green et al. 2009).

Acknowledgments.—Our research was supported by the Tennessee Wildlife Resources Agency, the University of Tennessee Institute of Agriculture, and the Tifton Veterinary Diagnostic and Investigational Laboratory of the University of Georgia. All research procedures followed approved University of Tennessee Institutional Animal Care and Use Committee protocol (1712), and field activities were authorized by the United States National Park Service (GRSM-2007-SCI-0014) and the Tennessee Wildlife Resources Agency (1990). We thank L. Whittington for assistance with molecular testing, E. C. Burton and A.C. Schmutzer for help with collecting samples, P. E. Super for coordinating sampling logistics in the Great Smoky Mountains National Park, and two anonymous referees for providing comments on initial drafts of the manuscript.

Amphibian Chytrid Fungus in Western Toads (*Anaxyrus boreas*) in British Columbia and Yukon, Canada

BRIAN G. SLOUGH
35 Cronkhite Road, Whitehorse, Yukon Territory, Y1A 5S9, Canada
e-mail: slough@northwestel.net

The amphibian chytrid fungus, *Batrachochytrium dendrobatidis* (*Bd*), appears to have a patchy pattern of occurrence, particularly at the northernmost extent of its distribution (Aanensen et al. 2009). In northwestern North America, *Bd* has been detected in Western Toads, *Anaxyrus boreas*, in southeast Alaska, USA (Adams et al. 2007), the Peace River district in northeast British Columbia, Canada (Raverty and Reynolds 2001), and in southwest British Columbia (Deguise and Richardson 2009). *Bd* also was found in Wood Frogs, *Lithobates sylvaticus*, in Kenai National Wildlife Refuge, Alaska (Reeves and Green 2006, Reeves 2008), and in Northern Red-legged Frogs, *Rana aurora*, from Vancouver Island, British Columbia (Adams et al. 2007). Conversely, *Bd* was not detected in Columbia Spotted Frogs (*Rana luteiventris*), Wood frogs, or Western Toads collected at several locations including the Chilkoot Trail National Historic Site, northwest British Columbia (Adams et al. 2007). Likewise, *Bd* was not found in Wood Frogs in Denali National Park (Chestnut et al. 2008), Innoko National Wildlife Refuge, or Tetlin National Wildlife Refuge, Alaska (Reeves 2008). However, small sample sizes and low prevalence may have affected detection at some sites (see Skerratt et al. 2008).

Amphibians within a large portion of the range of Western Toads at its northern limit in northern British Columbia (Matsuda et al. 2006) and the southeast Yukon Territory, Canada (Slough and Mennell 2006) have not been sampled for *Bd*. To address this gap, I sampled amphibians for *Bd* from 4 distinct populations in this region in 2007 and 2008, including Tutshi Lake, Atlin Lake and the Nakina River in northwest British Columbia, and the Coal River in the southeast Yukon Territory (Table 1).

Amphibians were located using visual encounter surveys and were captured by hand or dip net, which had been cleaned and dried between captures and disinfected with bleach between sites. Each animal was held separately prior to swabbing and was handled with a new pair of vinyl medical examination gloves and swabbed with a sterile 15 cm cotton-tipped swab (AMG Medical Inc., Montréal, QC) 5-times each below the throat, between the toes of the front feet, along the belly, thighs, around the drink patch and cloaca and between the toes of the hind feet. Each swab was air-dried for 5 min and placed tip down in a 1.5 ml microcentrifuge tube. Excess handle-length of the swab was broken off and the tube was sealed and stored frozen. Swabs were analyzed for *Bd* with a real-time PCR assay at either the British Columbia Ministry of Agriculture, Fisheries and Food, Animal Health Centre (2007 samples) or the University of Victoria, British Columbia (2008 samples) using the technique described by Boyle et al. (2004).

In 2007, seven of 20 toads from Atlin Lake and the Nakina River tested positive for *Bd*, and the Tutshi Lake samples were *Bd*-negative (Fig. 1). A Wood Frog from Atlin Lake and two Long-toed

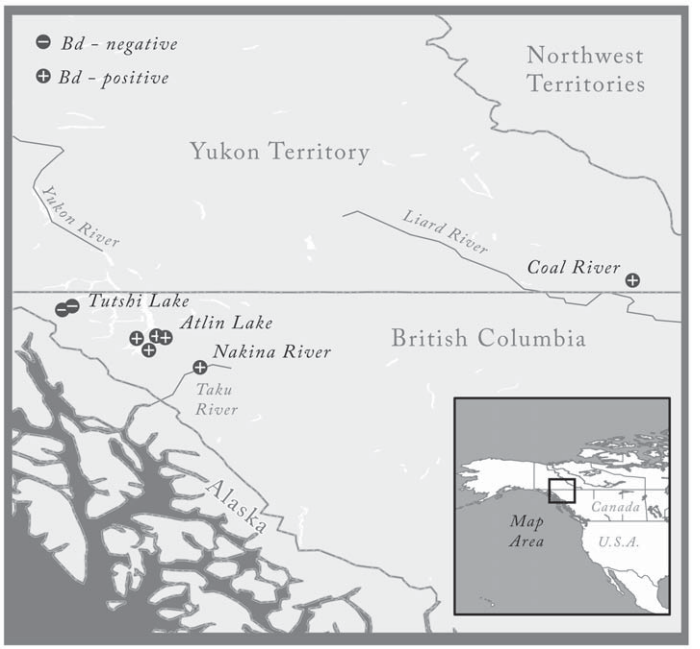

FIG. 1. Locations in British Columbia and Yukon, Canada where amphibians were sampled for the presence (+) of *Batrachochytrium dendrobatidis* (*Bd*) in 2007 and 2008. "–" indicates locations where *Bd* was not detected.

Salamanders (*Ambystoma macrodactylum*) from the Nakina River also tested negative. One of the *Bd*-positive Western Toads from Atlin Lake had sloughing skin on a thigh; otherwise no other individuals had visual signs of the disease such as lethargy or redness on the legs. In 2008, all 10 toad metamorphs from Atlin Lake, an adult toad, and six Wood Frogs from the Coal River, Yukon Territory, tested *Bd*-positive. Western Toad tadpoles from the Coal River were *Bd*-negative.

The pattern of patchy *Bd* occurrence at high northern latitudes is supported by these additional data from northern British Columbia and Yukon Territory. *Bd* was present in three Western Toad populations sampled in northwestern British Columbia and Yukon Territory but was not detected at Tutshi Lake (Fig. 1), the northwestern-most site surveyed, which coincidentally is only 10 km east of the Chilkoot Trail National Historic Site where amphibians previously sampled also were *Bd*-negative (Adams et al. 2007).

There is concurrent Western Toad breeding site monitoring at one of the study sites, the Atlin Warm Springs, at Atlin Lake, where there were eggs, larvae or metamorphs present demonstrating breeding activity in survey years 1988, 1996, 1998, 1999, 2001, 2005 and 2008, but no breeding activity or adults were observed in 2006, 2007 and 2009 (B. Slough, unpubl. data). This is a small population, with no more than 25 adults and 8 egg clutches observed at one time, however it has demonstrated long-term persistence. Other observations of toads at this site were made in 1924 (Slevin 1928; MVZ 9478–9483, Museum of Vertebrate Biology, University of California, Berkeley), 1952 (Cook 1977), 1962 (RBCM 1273, Royal British Columbia Museum, Victoria), 1979 (CMNAR 21852, Canadian Museum of Nature, Ottawa), 1980 (RBCM 1389) and 1993 (Mennell 1997). These data indicate that the breeding population may have suffered recent losses, and although *Bd* may be contributing to this, several alternative or interacting factors warrant consideration (e.g., climate change; Slough 2009), especially due to the location of this area at the margin of the species' range. The general status rank of the Western Toad is *Sensitive* in British Columbia and the Yukon (Canadian Endangered Species Conservation Council 2006), and it is protected under the federal *Species at Risk Act* after being designated *Special Concern* (COSEWIC 2002). The effect of *Bd* on northern amphibian populations, especially

Batrachochytrium dendrobatidis (*Bd*) has been associated with global amphibian population declines and occasionally with species extinctions (Daszak et al. 1999). Further, recent evidence suggests that surviving amphibian communities may persist with sublethal infections (Rettalick et al. 2004). Although *Bd* has been detected in amphibians in Great Smoky Mountains National Park (GSMNP; Chatfield et al. 2009), USA, mortality associated with chytridiomycosis has not been reported.

The Southern Appalachian Mountain Range, where GSMNP occurs, is known for its amphibian species richness (Dodd 2004). Within the GSMNP, Cades Cove, Tennessee, is one of the most highly visited sites by tourists, and thus an area where anthropogenic stressors (e.g., introduction of chemical agents or novel pathogens) may impact native species. Although amphibian mortality was observed in Cades Cove from 1999 to 2001, these mortality events were attributed to pathogens other than *Bd* (Dodd 2004; Rothermel et al. 2008). On 5 April 2009, a recently deceased adult male *Rana palustris* was found in a pond in Cades Cove (35.606667ºN, 83.816944ºW) while conducting field surveillance for *Ranavirus*. The animal was collected and shipped overnight on ice to the University of Georgia, Veterinary Diagnostic and Investigational Laboratory for diagnostic evaluation.

Gross examination revealed only mild (ca. 48 h under refrigeration post field collection) postmortem autolysis. Grossly there was diffuse erythema (reddening) on the ventromedial legs and random petechia (pin-point hemorrhages), ecchymosis (red blotches), and irregular patches of discoloration elsewhere on the ventral body (Fig. 1A). Vascular congestion was noted in the kidneys but other organs appeared normal. Sections of all organs were collected and fixed in 10% phosphate-buffered formalin, embedded in paraffin, cut at 4 μm sections, stained with hematoxylin and eosin, and examined microscopically. Additionally, sections of skin lesions and toes were collected for qPCR and conventional PCR for *Bd*, and sections of skin lesions, liver and kidney were collected for

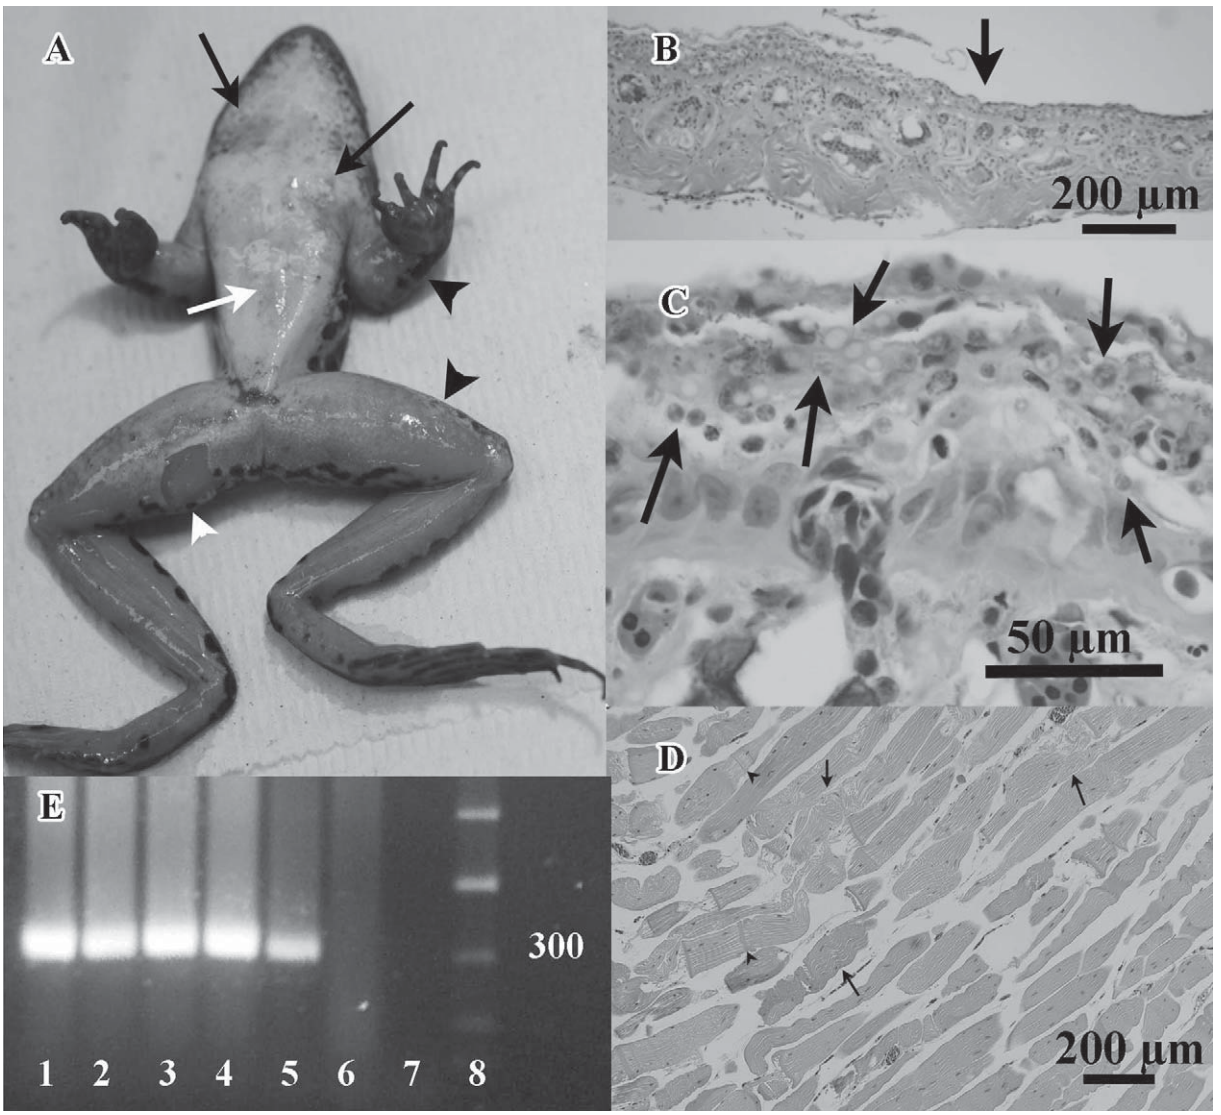

FIG. 1. A) Gross changes observed in *Rana palustris* found dead in Great Smoky Mountains National Park, Tennessee, USA. There is diffuse erythema on the ventromedial legs (black arrowheads) and random petechia, ecchymosis (white arrow), and irregular patches of discoloration (black arrows) elsewhere on the ventral body. The white arrowhead indicates an area of post-mortem tissue sampling. B) Photomicrograph of a hematoxylin and eosin (H&E) stained section of skin from the frog showing epidermal proliferation. The area to the left of the arrow is more proliferative and the area to the right is more normal. C) Closer view of the proliferative skin area in B (H&E stain), showing the organisms consistent with *Batrachochytrium dendrobatidis* zoospores (arrows). D) Photomicrograph of an H&E stained section of skeletal muscle subjacent to the skin lesions, and showing swollen fibers that had lost cross-striations and were often fragmented (arrows), and occasional contraction bands (arrowheads). E) Gel electrophoresis of the PCR products isolated from skin and toe samples collected from the frog pictured in A. The 300-bp products were consistent with *Bd*. Lanes 1 and 2 are Frog Sample 1, Lanes 3 and 4 are Frog Sample 2, Lane 5 is the Positive *Bd* Control, Lane 6 is the Negative Tissue Control, and 7 is Negative Control, Lane 8 is the molecular weight marker.

qPCR and conventional PCR for *Ranavirus*. Chytrid qPCR was performed using the method described by Boyle et al. (2004), and conventional PCR was performed following the protocol by Annis et al. (2004). *Ranavirus* qPCR was performed using the protocol by Picco et al. (2007), and conventional PCR was performed following the protocol by Mao et al. (1997).

Histologically, the epidermis was multifocally thickened (2–4 cell layers; Fig. 1B) with intracytoplasmic 3–5 μm round organisms (Fig. 1C) consistent with *Bd* organisms (thalli). This type of lesion was consistently found in the epidermis overlying the digits and in the skin lesions observed grossly. The skeletal muscles subjacent to the skin lesions had swollen fibers and patches of myofiber disarray, fragmentation, and loss of cross-striations (Fig. 1D). Conventional PCR was positive for *Bd* (Fig. 1E), but negative for *Ranavirus*. Likewise, qPCR was positive for *Bd*, but negative for *Ranavirus*.

The histological and molecular findings were consistent with chytridiomycosis caused by the amphibian pathogen *Bd*. Sensitivity to *Bd* varies by amphibian species (Blaustein et al. 2005), and may be partially attributed to differences in skin antimicrobial properties (Woodhams et al. 2004). Ultimately, chytridiomycosis is believed to interfere with osmoregulation (Voyles et al. 2007), which leads to muscular degeneration and eventually death (Miller et al. 2008). Other factors (e.g., environmental contaminants,

climate change) are hypothesized to exacerbate the effects of or make amphibians more susceptible to this pathogen (Bosch et al. 2007; Davidson et al. 2007).

We are uncertain what factors contributed to this *R. palustris* developing chytridiomycosis. Rothermel et al. (2008) found that 23 of 35 *R. palustris* collected from the southeastern United States were positive for *Bd*; however, chytridiomycosis was not found. In a Canadian survey, *Bd* prevalence in *R. palustris* was found to be low (3%; Ouellet et al. 2005). Given the findings from these studies and the lack of detection of other pathological changes in the *R. palustris* in our study, an exogenous stressor or combination of stressors (e.g., chemical exposure, habitat change, breeding) may have contributed to the development of chytridiomycosis in this case.

The finding of chytridiomycosis in this *R. palustris* verifies the need for continued surveillance and testing of amphibian populations in the GSMNP. Given the wealth of amphibian biodiversity in the GSMNP, this location serves as an ideal place to study the variation in pathogen prevalence and species susceptibility of amphibian populations. The co-occurrence of two emerging amphibian pathogens (*Ranavirus* [Dodd 2004] and *Bd*) in Cades Cove warrants continued monitoring of amphibian breeding ponds in this highly visited area of GSMNP.

Acknowledgments.—We thank Ben Dyer for assistance in field collections, and the staff of the University of Georgia Veterinary Diagnostic and Investigational Laboratory for assistance in tissue processing, especially Lisa Whittington, Diane Rousey, and Kim Bridges. This study was conducted with permission from the National Park Service (#GRSM-2008-SCI-0056) and an approved University of Tennessee animal care and use protocol (#1763). Funding for field collection was provided by the Ecology and Evolutionary Biology Department at the University of Tennessee.

Hellbenders (*Cryptobranchus alleganiensis*) are one of the largest salamanders in North America, averaging 29–51 cm in total length, but reaching up to 70 cm (Nickerson and Mays 1973; Conant and Collins 1998; Johnson 2000). The Eastern Hellbender (*C. a. alleganiensis*) ranges from New York State south to Georgia, and west to Missouri, whereas the Ozark subspecies (*C. a. bishopi*) is only found in a few locations in south central Missouri and northern Arkansas (Firschein 1951; Pfingsten 1990; Petranka 1998). Serious population declines have targeted the Ozark Hellbender as a conservation priority species by numerous institutions (e.g. government agencies, universities, zoos, etc.). These institutions have spent considerable effort to recover the species in Missouri (Wheeler et al. 2003; Briggler et al. 2007). Due to the drastic decline in number of wild Hellbenders in Missouri, captive propagation was one necessary component to the recovery of the species in which the Ron Goellner Center for Hellbender Conservation at the Saint Louis Zoo was created. Numerous Hellbenders were removed from the wild and moved to their new artificial stream raceway to facilitate long-term propagation efforts. As with many propagation efforts, various aspects of Hellbender biology are being investigated in detail at the St. Louis Zoo, including ecological nutrition and digestive physiology, to better address long-term health needs of this captive breeding stock. Hellbenders are fully aquatic, spending most of their life under flat rocks in stream bottoms (Nickerson and Mays 1973; Johnson 2000). Diet consists of a variety of aquatic prey including small fish and insects, but a majority of the diet comprises whole crayfish, consumed in their entirety (Nickerson and Mays 1973; Peterson et al. 1989; Petranka 1998).

The primary purpose of this study was two-fold: 1) to obtain details on a preferred food item of Hellbenders, for which no nutritional composition data exist (crayfish plus shell) as a basis for assessing nutritional status in the wild; and 2) to compare native food composition with substitute food items used in captivity. A secondary goal was to investigate possible factors that may underlie any differences noted in chemical composition. These initial data might provide useful information for optimizing nutritional health and dietary management of Hellbender and other crayfish-eating species (e.g., storks; Negro and Garrido-Fernandez 2000).

Samples.—Three species of native crayfish were used in this study. Long-pincered Crayfish (*Orconectes longidigitus*), Spothanded Crayfish (*O. punctimanus*), and Ringed Crayfish (*O. neglectus*) were opportunistically collected from two locations in close proximity on the North Fork of the White River, Missouri, USA in August 2006 and September 2007 (N = 21 total samples). Crayfish were transported in buckets of stream water and maintained overnight before being identified to species, weighed, measured, and processed for nutrient analysis. Three individual crayfish were not positively identified and were included in samples as unidentified.

Feeder crayfish obtained locally in 2005 and 2006 comprised a single species, Northern Crayfish (*Orconectes virilis*), from Paul's Bait Shop (PBS, N = 9; St. Louis, Missouri, USA) or directly from Ozark Fisheries (OF, N = 7; Stoutland, Missouri USA). In 2007, *Procambarus paeninsulanus* (Peninsula Crayfish) from Florida (FL, N = 9) were added as a substitute feeder species, and *O. virilis* were also collected for analysis from ponds on the grounds of the Saint Louis Zoo as part of a larger population study for potential sustainable harvest (SLZ, N = 21). SLZ crayfish of three body sizes (see below) were sampled from two sites (North and South Lakes) during either summer (Jun–Aug) or fall (Sep–Oct) 2007. Purchased crayfish were shipped or transported in water overnight, and processed within 24 h of receipt. Crayfish acquired on zoo grounds were collected in the morning from traps set the previous day using canned cat food as bait, and sampled within 24 h. Because Hellbenders consume crayfish in toto, an additional subset of trapped crayfish from SLZ (N = 24) were dissected to determine percent contribution of nutrients from shell vs. remainder of the body by weighing and analyzing portions separately, and water and substrate samples were taken for chemical analysis at the two sites.

Laboratory Processing/Analyses.—Animals were weighed to the nearest 0.1 g, and carapace and tail-to-rostrum length (TR) measured to the nearest 0.01 cm with calipers. Crayfish were categorized as small (<2.5 cm total length), medium-sized (2.5 to 5 cm total length), or large (>5 cm). All crayfish were euthanized by decapitation, then head and body were homogenized together in a food processor (Toastmaster Chopster). Subsamples of homogenate (0.5 g in duplicate) were taken immediately and extracted via previously described methods for meat samples (Barker et al. 1998) to determine vitamin A (as retinol), E (as α-tocopherol), and total carotenoids. Extracts were sealed in cryovials, stored in an ultracold freezer (-20°C), and sent to Arizona State University for analysis via HPLC following the methods

of McGraw et al. (2006). Pigment extracts were resuspended in 200 µl mobile phase (42:42:16% (v/v/v) methanol : acetonitrile : dichloromethane) and injected into a Waters Alliance 2695 HPLC system (Waters Corporation, Milford, MA) fitted with a Waters YMC Carotenoid 5.0 µm column (4.6 mm × 250 mm) and a built-in column heater set at 30°C. A three-step gradient solvent system was used to analyze both xanthophylls and carotenes in a single run, at a constant flow rate of 1.2 ml min-1: first, isocratic elution with the aforementioned mobile phase for 11 min, followed by a linear gradient up to 42:23:35% (v/v/v) methanol : acetonitrile : dichloromethane through 21 min, held isocratically at this condition until 26 min, and finishing with a return to the initial isocratic condition from 26 to 29.5 min. Data were collected from 250 to 600 nm using a Waters 2996 photodiode array detector. Pigments were identified by comparing their respective retention times and absorbance maxima (λmax) to those of reference carotenoids run as external standards.

Subsamples (1.0 g) from 10 randomly-selected farmed crayfish (*Orconectes virilis*) were frozen for determination of fatty acid content at the University of Missouri-Columbia; a frozen Pacific Krill (*Euphasia pacifica*) sample was also sent for comparison since krill are often used in feeding very small salamanders (J. Ettling, pers. comm.). Total lipids were extracted with chloroform: methanol (2:1 v/v) after samples were homogenized in 10 mM EDTA. Lipids were methylated with freshly made 5% methanolic HCl. Fatty acid methyl esters were extracted with hexane. Pigments and residual water were removed from each sample with the addition of 0.1 g each of anhydrous sodium sulfate and activated charcoal. Methyl esters were analyzed by gas chromatography using an HP 5890A instrument with a 30-meter capillary column (Omegawax 250; Supelco, Bellefonte, PA) according to the methods of Sukhija and Palmquist 1988. Individual fatty acids were identified using retention times of standards (i.e., Omegawax, PUFA-II, PUFA-I; Supelco).

Remaining sample homogenates were freeze-dried (Labconco Freezone 4.5) to determine water content, and dried, ground samples were sent for proximate analysis (crude protein, crude fat, fiber fractions, ash) and minerals to Dairy One Forage Lab (Ithaca, NY). Substrate mineral content was determined at the Amino Acid Laboratory, University of California (Davis, California; data not presented). Differences in nutrient composition by species (stream-caught) or source/location within species (pond-reared) were evaluated with Mann-Whitney tests at a significance level of 0.05 (Snedecor and Cochran 1967). For the STZ crayfish samples only, percentage data were arcsine transformed to approximate normal distribution, and seasonal, body size, and sampling location differences in nutrient composition were compared by analysis of variance.

Wild-captured crayfish sampled from Hellbender habitats varied widely in size compared to those utilized as food for captive salamanders at the Saint Louis Zoo (Table 1). Regardless of species, size ranges encompassed the small and medium body size criteria preferred by zoo managers. Specific preferences of crayfish prey size have not been determined for Hellbenders; presumably crayfish must be suitably sized to trigger a feeding response, yet not too large to defend themselves against ingestion. Although similar in carapace length to those obtained from commercial suppliers, Northern Crayfish from the zoo ponds in this study contained ash-free dry weight (AFDW) similar to that reported from wild-caught Virginia *O. virilis* (~3.7 g vs. 3.8 g, respectively; Mitchell and Smock 1991) and almost twice the AFDW calculated for the fisheries-reared crayfish (~2.0 g from PBS, ~1.5 g from OF).

Body sizes did not differ between *O. virilis* samples collected for dissection at the two STZ sites, hence data were combined (mean weight = 25.2 ± 5.4 g). Of total body composition, shell comprised 61.5 ± 5.7% of whole body mass, whereas meat and body fluids reflected the remaining 38.5 ± 5.7% (wet basis). Shells averaged 31.2 ± 4.3% dry matter (DM) (or 68.8% water), and meat averaged 17.8 ± 2.1% DM, approximately 82.2% water.

Proximate Composition.—Overall, crayfish provided crude protein concentrations in excess of the requirements determined for domestic carnivores, fish and shellfish (ca. 15 to ~40% of DM; Zootrition 2006). Protein and fat, as fractions of whole body mass, are typically inversely related when evaluating composition of whole vertebrate prey. This pattern was not apparent in crayfish, possibly due to the much greater contribution of both ash and carbohydrate fractions (from shells) in crayfish compared to vertebrate prey species. Total ash reported in whole vertebrate prey DM ranges from 7.5 (juvenile hamsters) to 17.5% (snowshoe hare) as opposed to 30–45% in crayfish, whereas carbohydrate content is generally negligible (Dierenfeld et al. 2002). Additionally, the crude fat content of most whole prey (range 5–45% of DM, but typically 15–35%, depending on species and age of prey; Dierenfeld et al. 2002) is considerably higher than recommended minimum dietary levels (~5 to 10% of dry matter, DM) for domestic carnivores (NRC 2006). Crayfish contained some of the lowest fat concentrations measured across a wide variety of whole prey consumed by carnivores, with both wild-caught and farmed crayfish averaging <5% fat (DM basis, Tables 2 and 3). This may be important for overall energetics and nutritional balance, as amphibians and other poikilotherms have a lower metabolic rate than homeotherms, hence require fewer calories per unit body mass. Thus low-fat, lower nutrient density dietary ingredients may be entirely appropriate for Hellbenders, but actual nutritional requirements remain uncharacterized for amphibians and most reptiles. As with all species—but perhaps particularly so for low-energy amphibian species—the feeding of higher-fat dietary ingredients in captive management programs should be carefully controlled to minimize risk of obesity or health conditions associated with excess body condition.

Nonetheless, some fat, and particularly essential fatty acids (EFAs) are required in the diet, hence our analysis provides baseline information on fatty acid content of whole crayfish (Table 4). Fatty acids are the primary constituent of most lipids, and can be deposited in animal tissues with minimal modification from diets; fatty acid signatures are often used to differentiate and understand trophic interactions in aquatic ecosystems (Iverson et al. 2002). Although the essential fatty acid (EFA) requirements of salamanders have not been determined to our knowledge, minimum dietary recommendations of domestic carnivores for two of the omega-6 EFAs, linoleic acid (18:2n6) and arachidonic (20:4n6), have been set at 0.5 and 0.2% of dietary DM, respectively (NRC 2006). Crayfish in this study contained 9% of total FA as linoleic, and 6.5% as arachidonic acid (see Table 4). Converting FA data reported here to a comparable dietary DM basis yields 0.3%

TABLE 1. Size (mean ± SD; range in parentheses) parameters of crayfish sampled to determine nutrient composition of whole crayfish available as food to Ozark Hellbender (*Cryptobranchus alleganiensis bishopi*). nd = not determined.

Species	N	Mass (g)	Carapace Length (cm)	Tail–Rostrum Length (cm)

Spothanded Crayfish (*Orconectes punctimanus*)	4	23.12 ± 6.31 (13.62–31.04)	5.96 ± 2.91 (3.57–9.70)	7.97 ± 0.47 (7.60–8.50)
Unidentified (*Orconectes* species)	3	8.35 ± 5.33 (3.95–14.27)	2.69 ± 0.55 (2.11–3.20)	5.46 ± 1.11 (4.26–6.43)
Farmed				
Northern Crayfish - Local bait shop (*Orconectes virilis*)	9	12.11 ± 3.56 (6.19–16.69)	7.68 ± 0.82 (6.0–8.9)	nd
Northern Crayfish - Ozark Fisheries (*Orconectes virilis*)	7	9.64 ± 2.13 (5.42–16.88)	7.14 ± 0.50 (6.0–8.4)	nd
Northern Crayfish - SLZ ponds (*Orconectes virilis*)	21	21.04 ± 8.77 (7.74–38.64)	7.39 ± 2.27 (3.93–18.19)	10.41 ± 2.71 (6.88–15.00)
Peninsula Crayfish - Florida (*Procambarus paenenisulanus*)	9	6.13 ± 2.85 (2.92–9.66)	2.94 ± 0.83 (2.10–4.83)	5.55 ± 0.79 (4.26–6.43)

linoleic acid (3% crude fat (Table 3) * 0.09), and 0.2% arachidonic (3% fat *0.065). Assuming that amphibian carnivores have similar fatty acid requirements as domestic animals, and since fat has ~2 times the caloric value of carbohydrates or protein, crayfish would provide about 0.5% of dietary energy as linoleic acid, a value that would be considered borderline for meeting EFA requirements in the absence of any preformed arachidonic acid (AA). However, the presence of 0.2% AA determined in the crayfish should be sufficient to meet the requirements for omega-6 polyunsaturated FA for most animals that might be consuming crayfish as a primary food source. Marine krill, however, appear to provide insufficient levels of both EFAs (Table 4). Both whole crayfish and whole krill contained relatively high concentrations of polyunsaturated fatty acids (PUFA) (22–32% of total fatty acids as PUFA). PUFA can be more prone to oxidative degradation compared with more saturated fats, thus may require higher levels of dietary antioxidants. By comparison, saturated fats were much higher in the marine krill (45.4%) compared with fresh water crayfish (32.4%), comprising almost half of total fatty acids quantified. Additionally, the omega-3:omega-6 fatty acid ratios measured in crayfish compared with krill vary considerably (Table 4), with omega-6 fatty acids about 10-fold higher in crayfish compared with krill; these two feed types are not nutritional equivalents. In particular, omega-3:omega-6 ratios/composition may have health implications for captive feeding programs of Hellbenders, particularly regarding immune function (Fritsche 2006), which should be investigated further. Interestingly, meat from farmed crayfish contained higher concentrations of all fatty acids compared with meat from wild crayfish reported in the USDA Nutrient Database (USDA 2009), further suggesting that captive dietary management may certainly influence composition, and should be considered when raising species as food for other animals.

Regarding carbohydrate (CHO), fractions, while most vertebrate whole prey are not considered to contain substantial concentrations of simple sugars, dietary fiber (measured as crude fiber, acid detergent fiber, and/or neutral detergent fiber), may be measurable in gastrointestinal contents of herbivorous prey species. In the case of crayfish, the chitinous exoskeleton is a chemical matrix comprising polysaccharide units (similar to plant cellulose) and protein. It is unclear whether the exoskeleton provides a source of dietary nutrients to Hellbenders; chitinase enzyme activity has not been reported, and digestibility trials have not been performed. Hellbenders have the ability to regurgitate exoskeleton fragments—identification of such samples is a technique routinely used for feeding ecology studies (Peterson et al. 1989). The dietary fiber (CHO) measured in crayfish samples (~14 to 24–30% of DM, depending on fraction considered from Tables 2 and 3) derives from the exoskeleton, and likely provides physical fill and/or a source of mineral nutrition to Hellbenders consuming whole crayfish, rather than readily available calories.

Mineral Content.—In general, the wild-caught crayfish (Table 2) contained more inorganic constituents (ash) compared with commercially-reared crayfish (Table 3; 47.16 versus 36.81%, respectively) and thus may provide better dietary mineral levels. The shell contributed 79.6% of measured ash, ~90% of Ca, and 31–64% of other minerals (with the exception of S, where 80% was present in meat). Northern Crayfish sampled from SLZ were more similar to wild-captured crayfish than were those sampled from either PBS or OF, and differed significantly ($P < 0.05$) in

[ab] Means in the same row without a common superscript letter differ (Mann-Whitney test; $P < 0.05$).

total ash, Ca, Cu, and Fe from those groups (Table 3). Other significant differences between the SLZ-pond and fishery-pond reared crayfish (Mg, K, S levels) may reflect differences in water or substrate quality, and/or result from unspecified holding and feeding schedules at the bait shop. Macromineral requirements (as a percentage of dietary DM) for growing mammal and bird species (Ca, 0.4 to 1.2%; Mg, 0.03 to 0.1%; P, 0.3 to 0.6%; K, 0.2 to 1.4%; and Na, 0.05 to 0.4%; Zootrition 2006) appear to be met by any of the crayfish analyzed in this study.

Wide variability among and within samples in trace element composition is evident and likely due to multiple factors including limited sample size, differing original dietary trace mineral levels, and possibly habitat/substrate variability. Mineral concentrations in water and substrate did not differ between sampled sites at SLZ (data not shown), but neither water, substrate, nor food samples were obtained from any other crayfish group, so source of variation is unknown at this time. Dietary requirements for Cu range from about 3 to 5 mg/kg DM for domestic carnivores (NRC 2006); and high levels can be toxic. In particular, the high Cu level documented in some crayfish (>100 mg/kg) is of potential health concern. Although LC50 is not directly comparable to LD50, toxicity (based on survival) has been determined between 40 and ~800 µg/L for *Ambystoma* spp. salamanders (Sparling et al. 2000), a magnitude lower than dietary levels measured in this study. While Cu LD50 has not been reported for salamanders, dietary tolerance of this nutrient is 15 and 40 mg/kg for sheep and cattle, respectively, and 100 mg/kg for fish (NRC 2005). Northern Crayfish could have been exposed to copper from commercial fish foods and fish wastes in confined ponds, which may have affected their overall composition. Copper sulfate is often added as an algaecide and may contribute to crayfish body composition (38% of Cu was found in the shell); hence, aquatic environmen-

tal quality is critical both directly and indirectly to the health of the Hellbender. Similarly, iron requirements for carnivores range from ~30 to ~100 mg/kg DM (NRC 2006), and excessive levels may interfere with bioavailability of other trace minerals. Recommended levels of bioavailable Mn and Zn (5 mg/kg, and 10 to 50 mg/kg, for cats and dogs, respectively; NRC 2006) would likely be met by crayfish as a dietary staple, but nutrient requirements and dietary interactions in salamander nutrition remain to be investigated.

Fat-Soluble Nutrients.—Vitamin A levels tend to increase with age/maturity in vertebrate prey through accumulation in body stores, particularly liver. Body size and vitamin A content were uncorrelated in our study; however, vitamin A levels were exceptionally high in farmed (OF) and baitshop (PBS) sourced crayfish (Table 3; 1.6 to 2.9 million IU/kg DM [0.3 μg retinol = 1 IU]) as well as in 3 of 4 wild crayfish species (~300,000 to 500,000 IU vitamin A/kg DM). The unidentified species and the SLZ pond-caught crayfish contained vitamin A concentrations ranging between ~26,000 and 40,000 IU/kg DM. Dietary requirements for vitamin A in domestic carnivores are approximately 4000 to 11,000 IU/kg DM (NRC 2006); presumed upper safe limits of this nutrient range from 33,000 IU/kg (dogs) to 100,000 IU/kg DM (cats) (NRC 1987). Clearly more information is needed on safe levels of this nutrient for salamanders (and crayfish), but it appears likely that diets fed to the farmed animals may have contributed to the high body levels found in this study.

Vitamin E concentrations were quite high in all crayfish sampled; crayfish meat has been previously shown to be a good source of this nutrient (USDA 2009) and may provide an important dietary antioxidant. Vitamin E levels in crayfish (160–486

TABLE 4. Fatty acid composition (mean ± SD) of whole Missouri native crayfish (Northern Crayfish, *Orconectes virilis*), compared with whole Pacific Krill (*Euphasia pacifica*).

Fatty Acid Name	Fatty Acid*	Crayfish (N = 10)	Krill (N = 1)
		% of total fatty acids

	n3:n6	0.85:1	7.8:1

* First number denotes the # of carbons in the fatty acid; 2nd # denotes the total # of double bonds; the number following "n" refers to the position of the first double bond relative to the methyl- or "omega"–end of the fatty acid.

mg/kg DM, calculated 240–729 IU/kg) consistently exceeded dietary requirements established for domestic carnivores (30–50 IU/kg; 1 mg natural source vitamin E = ~ 1.5 IU) fed diets containing moderate levels of polyunsaturated fats (PUFAs). High dietary PUFA (as found in crayfish), however, may increase the vitamin E requirement up to 5-fold due to the high oxidative potential of these fats; vitamin E can be depleted as it is utilized as a biological antioxidant. Vitamin E deficiency has been shown to adversely impact reproduction and immune function in other species (Dierenfeld and Traber 1992). Hence these high concentrations of vitamin E may be beneficial to health of Hellbenders, but require further investigation.

The only nutrient category that differed significantly among wild-caught crayfish species was total carotenoid concentration (Table 2), and unfortunately, this was compared with the species that remains unidentified. Carotenoid content measured is likely an artifact of small sample size, but may reflect real differences in feeding habits among crayfish species. *O. punctimanus* appears much broader in its habitat and possibly feeding requirements compared to other species, (MOFWIS 2008) and thus may be able to consume a diet containing higher levels of carotenoid pigments, but must be quantified further in more controlled studies. Diets fed in the fisheries pond(s) quite likely also contributed to the high levels of vitamins and carotenoids measured in the crayfish. It remains unclear, however, whether these higher nutrient levels are beneficial or detrimental to the salamanders consuming crayfish, as both vitamin A toxicity and deficiency can negatively impact health and reproduction. Vitamin A concentrations are lower in native crayfish or pond-captured crayfish compared with those sampled from farm-reared populations, but ranges varied by levels of magnitude, and, in general were higher than documented dietary requirements for carnivorous species in all samples – regardless of origin. Some of these concentrations are in ranges considered toxic for other species; to date, salamander dietary vitamin A nutrient requirements are unknown. Controlled feeding trials should be conducted and/or tissue levels of fat-soluble nutrients should be monitored to determine nutrient interactions and evaluate status. One potentially negative factor associated with low-fat diets (as found in crayfish) may be lower absorption of fat-soluble vitamins; this possibility should be investigated in future studies with Hellbenders.

Sources of variability in nutrient parameters measured in the SLZ crayfish found season (summer vs. fall) to be significant only in crude fat content ($P < 0.01$); location significantly impacted Cu ($P < 0.01$), Zn ($P < 0.01$), and P ($P < 0.001$) levels, even though trace mineral and water phosphate levels did not vary between the two sites (data not shown). Body size (hence, age/particular molt) had the greatest impact on both proximate and mineral nutrient composition of Northern crayfish at the Saint Louis Zoo, affecting crude protein ($P < 0.001$), ash ($P < 0.001$), Ca ($P < 0.05$), K ($P < 0.001$), Na ($P < 0.05$), P ($P < 0.05$), Cu ($P < 0.001$), Mn ($P < 0.05$), and Zn ($P < 0.01$) content. Larger crayfish contained higher levels of proximate nutrients (protein, fat, and ash) as well as macrominerals Ca, K, and Na compared to smaller animals. Phosphorus content, however, was higher in smaller crayfish, as were levels of trace minerals (Cu, Mn, and Zn). Locally harvested crayfish represented a nutritionally superior food for captive Hellbender compared to fisheries-reared individuals, and were closer in chemical composition to species found in native habitats. Sustainable local harvest should be explored as a viable alternative feeding option and as a way of reducing fossil fuel (transportation) costs.

These data provide preliminary detail on the nutrient composition of whole crayfish eaten by Hellbender, but clearly species, size, and habitat of origin impact the nutritional content of crayfish (and likely other aquatic prey species) eaten by Hellbenders. The chemical composition of native, as well as substitute, food items must be considered integral to the development of optimal diets for this species, and monitoring prey composition can provide strong bioindicators of habitat quality. In addition to crayfish, Hellbenders also eat small fish, lamprey, worms, insects, snails, mollusks, tadpoles, and fish entrails in nature (Nickerson and Mays 1973; Peterson et al. 1989; Petranka 1998); in captivity, they are fed black worms, krill, and fish along with crayfish (J. Ettling, pers. comm.). Intake, utilization, growth response trials, and health assessments to these varied whole prey items, and mixed diets, should provide valuable management guidelines that can assist in captive propagation, habitat evaluation, conservation and ultimate recovery of these unique and threatened salamanders. Characterization of both ex situ and in situ diets remains a critical component underlying health, reproduction, and recovery program management.

Acknowledgments.—We thank R. Goellner for his support in early stages of this investigation, the field conservation team including K. Goellner, K. Larson, J. Kiger, Y. Huang, J. Utrup, R. Junge and M. Wanner for assisting with the capture of wild-caught crayfish for this study, and A. Braddy, C. Chavez, C. Resimius, T. Rivers, V. Spradling, and S.

Tomasic for assisting with sample collection, preparation, analysis, and data organization. S. Blake provided helpful statistical guidance.

NATURAL HISTORY NOTES

The Natural History Notes section is analogous to Geographic Distribution. Preferred notes should 1) focus on observations in the field, with little human intrusion; 2) represent more than the isolated documentation of developmental aberrations; and 3) possess a natural history perspective. Individual notes should, with few exceptions, concern only one species, and authors are requested to choose a keyword or short phrase which best describes the nature of their note (e.g., Reproduction, Morphology, Habitat, etc.). Use of figures to illustrate any data is encouraged, but should replace words rather than embellish them. The section's intent is to convey information rather than demonstrate prose. Articles submitted to this section will be reviewed and edited prior to acceptance.

Electronic submission of manuscripts is requested (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Figures can be submitted electronically as JPG files, although higher resolution TIFF or PDF files will be requested for publication. Please DO NOT send graphic files as imbedded figures within a text file. Additional information concerning preparation and submission of graphics files is available on the SSAR web site at: http://www.ssarherps.org/HRinfo.html. Manuscripts should be sent to the appropriate section editor: **Charles W. Painter** (amphibians; charles.painter@state.nm.us); **James Harding** (turtles; hardingj@msu.edu); **Jackson D. Shedd** (crocodilians, lizards, and *Sphenodon*; Jackson.Shedd@gmail.com); and **John D. Willson** (snakes; willson@uga.edu); and.

Standard format for this section is as follows: SCIENTIFIC NAME, STANDARD ENGLISH NAME (if available, for the United States and Canada as it appears in Crother [ed.] 2008. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico*. SSAR Herpetol. Circ. 37:1–84, available from SSAR Publications Secretary, ssar@herplit.com; for Mexico as it appears in Liner and Casas-Andreu 2008, *Standard Spanish, English and Scientific Names of the Amphibians and Reptiles of Mexico.* Herpetol. Circ. 38:1–162), KEYWORD. DATA on the animal. Place of deposition or intended deposition of specimen(s), and catalog number(s). Then skip a line and close with SUBMITTED BY (give name and address in full—spell out state names—no abbreviations). (NCN) should be used for common name where none is recognized. References may be briefly cited in text (refer to this issue for citation format). One additional note about the names list (Crother 2008) developed and adopted by ASIH-HL-SSAR: The role of the list is to standardize English names and comment on the current scientific names. Scientific names are

hypotheses (or at least represent them) and as such their usage should not be dictated by a list, society, or journal.

Recommended citation for notes appearing in this section is: Medina, P., and R. L. Joglar. 2008. *Eleutherodactylus richmondi*: reproduction. Herpetol. Rev. 39:460.

CAUDATA — SALAMANDERS

AMBYSTOMA CALIFORNIENSE (California Tiger Salamander). **COLORATION AND PATTERN.** During the winter of 2003–2004, we conducted a survey for California Tiger Salamanders on farm lands owned by the City of Santa Rosa and two private properties in Sonoma County, California, USA. We used 17 pit-fall drift fence arrays (1360 pitfalls) to capture salamanders. During the course of our survey we captured 114 adult (57 male, 57 female) and 65 subadult California Tiger Salamanders on the city-owned Kelly Farm, an adjacent property on Duer Road, and another property at the north end of the former Santa Rosa Air Center. Animals were not marked and some may have been recaptured during the course of the study. Here we report on observations of the color and color pattern of the salamanders we captured.

California Tiger Salamanders typically have a black ground color with distinctive rounded or irregular yellowish to whitish spots and bars (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 587 pp.; Stebbins 2003. Western Reptiles and Amphibians 3rd ed. Houghton Mifflin Co., Boston, Massachusetts, 533 pp.). All the individuals captured in our survey, however, had a chocolate brown ground color with no gray or black tones (Fig. 1A). One subadult individual captured in our survey completely lacked pale spots or bars and was a uniform dark brown above and below (Fig. 1B); all other subadults captured during our study exhibited a typical spotting pattern. To the best of our knowledge California Tiger Salamanders with a chocolate brown ground color have not been described in the literature. Individuals of this species completely lacking a pale spotting pattern similarly have not been reported.

Fig. 1. (A) Adult male *Ambystoma californiense* (SVL 103 mm; TL 225 mm) exhibiting spotted color pattern typical of the Sonoma County population. (B) Subadult (SVL 70 mm; TL 105 mm) lacking typical spotted pattern.

Submitted by **ERIC LICHTWARDT** and **TIMOTHY LACY**, LSA Associates, Inc., 157 Park Place, Point Richmond, California 94801, USA (e-mail eric.lichtwardt@lsa-assoc.com).

TARICHA RIVULARIS (Red-bellied Newt). **ENDOPARASITES.** *Taricha rivularis* occurs in northern coastal California from Sonoma and Lake counties north to Humboldt County (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians, 3rd ed. Houghton Mifflin, Boston, Massachusetts. 533 pp.). To our knowledge there are no reports of helminths in *T. rivularis.* The purpose of this note is to establish the initial helminth list for *T. rivularis*.

One adult male *T. rivularis* hand collected by MDD in Mendocino Co., California (123.8058°N, 39.4416°W, WGS 84, elev. 26 m) on 23 March 2009 was sacrificed and the digestive tract removed, opened, and examined under a dissecting microscope. Fourteen nematodes were found in the intestine, which were fixed in alcohol, cleared in glycerol on a microscope slide under a coverslip, and studied using a compound microscope. Of these, six were female nematodes from the small intestine identified as *Oswaldocruzia pipiens* and eight (five male, three female) from the large intestine were identified as *Cosmocercoides variabilis.* Nematodes were deposited in the United States National Parasite Collection (USNPC), Beltsville, MD: *Oswaldocruzia pipiens* (USNPC 101993); *Cosmocercoides variabilis* (USNPC 101992). The *T. rivularis* was not accessioned.

Cosmocercoides variabiis is a cosmocercid nematode found in North American salamanders, frogs, lizards, snakes, and turtles (Baker 1987. Occas Paps. Biol. Memor. Univ. Newfoundland 11:1–325). Some uncertainty exists for its hosts because of confusion between *C. variabilis* and *C dukae*, a molluscan parasite. Vanderburgh and Anderson (1987. Can. J. Zool. 65:1662–1665) demonstrated that the two species are distinct. The major difference in morphology for the two species is the number of rosette papillae in the male: *C. dukae* with 12 pairs, *C. variabilis* with 14–20 pairs. We have assigned these specimens to *C. variabilis* because males have 16 pairs of papillae. Infection occurs by skin penetration (Baker 1978. J. Parasitol. 64:765–766). All North American specimens of *Oswaldocruzia* have been referred to *O. pipiens* by Baker (1977. Can. J. Zool. 55:104–109). *Oswaldocruzia pipiens* is a strongylid nematode that is widely distributed and has been reported from frogs, toad, salamanders, lizards, and tortoises (Baker 1987, *op. cit.*). In the case of amphibians, transmission occurs by skin penetration (Baker 1978. Can. J. Zool. 56:1026–1031). *Taricha rivularis* represents a new host record for *O. pipiens* and *C. variabilis*.

Specimens were collected under authority of California state fishing license 029486-09 issued to Murray D. Dailey.

ANURA — FROGS

LIMNONECTES IBANORUM (Rough-backed River Frog). **DIET.** *Limnonectes ibanorum* is endemic to the island of Borneo, where it occurs in rainforest at elevations between 50 and 900 m (Inger 1966. Field. Zool. 52:1–402). Although this large frog (SVL to 13 cm) is common along clear, rocky streams of intermediate width (10–30 m) (Inger and Stuebing 2005. A Field Guide to the Frogs of Borneo. Natural History Publications [Borneo], Kota Kinabalu. 201 pp.), almost nothing is known about its ecology. According to Inger and Stuebing (2005, *op. cit.*), *L. ibanorum* feeds on large insects, crabs, and small lizards. The diet of its large (SVL > 9 cm) Bornean congeners, i.e. *Limnonectes ingeri, L. leporinus*, and *L. malesianus*, also includes frogs (Inger and Stuebing 2005, *op. cit.*; Malkmus et al. 2002. Amphibians and Reptiles of Mount Kinabalu [North Borneo]. Koeltz Scientific Books, Königstein. 424 pp.), but there are no reports of predation of frogs by *L. ibanorum*.

On 20 Sept 2007 at 2045 h, I observed an adult *L. ibanorum* (SVL 11.5 cm) catching and devouring an adult *Hylarana raniceps* (Fig. 1). The prey was ingested head first. The specimen of *L. ibanorum* was caught afterwards, measured, and released. The observation took place on the bank of the Nyipa River, Camp 1, Gunung Mulu National Park, Sarawak, Malaysia (ca. 150 m elev.).

I thank the Sarawak Forest Department for permission to conduct research in Gunung Mulu National Park. Fieldwork was supported by a grant from the German Academic Exchange Service (DAAD).

FIG. 1. *Limnonectes ibanorum* ingesting *Hylarana raniceps*, Gunung Mulu National Park, Sarawak, Malaysia.

TESTUDINES — TURTLES

CHRYSEMYS PICTA BELLII (Western Painted Turtle). **AS INTRODUCED PREDATOR.** The Western Painted Turtle occurs naturally in the central and northwestern United States and adjacent southern Canada but has been widely introduced to water bodies outside its natural range. Established populations and individual records in California presumably are introduced (Lever 2003. Naturalized Reptiles and Amphibians of the World. Oxford University Press; Stebbins 2003. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin Co., Boston, Massachusetts).

At 1600 h on 15 February 2007 an adult (782.8 g) *Chrysemys picta bellii* was found in Tracy Lake, San Mateo Co., California. When first observed, the turtle was in shallow water with a dead Pacific Chorus Frog (*Pseudacris regilla*) in its mouth. The condition of the frog suggests it was captured alive, rather than scavenged. It is perhaps significant that this turtle was eating a native frog in Tracy Lake, which supports a breeding population of the threatened California Red-legged Frog *(Rana draytonii)*. The Western Pond Turtle (*Actinemys marmorata*), which is listed by California as a Species of Concern, has also been observed in this lake. The introduced Red-eared Slider *(Trachemys scripta elegans)* has been established in this area for years, but to our knowledge this is the first report of *C. p. bellii* for this area. The impact of introduced turtles on native amphibians through direct predation remains unknown. The impact of Painted Turtles as a competitor of Western Pond Turtles is also unknown, but the latter are also known to feed on native anurans (Bury 1986. J. Herpetol. 20:515–521). Frogs have been previously noted in the diet of *C. picta* (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Inst. Press, Washington, DC) but may not be a significant food source. No frogs were detected in the stomachs of 46 *C. picta* collected in Michigan (Knight and Gibbons 1968. Am. Midl. Nat. 80[2]:558–562).

The turtle and frog were collected under California Department of Fish and Game Scientific Collecting Permit 008139 and deposited in the collections at the California Academy of Sciences.

EMYDOIDEA BLANDINGII (Blanding's Turtle). **PREDATION.** Neonate turtles, including *Emydoidea blandingii*, are known to have many predators. The dissection of Bullfrog (*Lithobates [= Rana] catesbeianus)* stomachs occasionally reveals the remains of hatchling turtles of various species, and *L. catesbeianus* has previously been observed in unsuccessful pursuit of hatchling *E. blandingii* (Bleakney 1963. Can. Field Nat. 77:67–76). Herein we report evidence of the successful predation of a hatchling *E. blandingii* by an adult *L. catesbeianus*.

On 28 August 2006, 12 hatchling *E. blandingii* emerged from

a protected nest at Winous Point Marsh, Ottawa County, Ohio, USA. The hatchlings were outfitted with 0.5 g radio transmitters and released at the nest site the following day. On 11 September we tracked one of these hatchlings to an agricultural ditch ca. 440 m W of the nest. Over several minutes we followed this individual's signal as it evaded our capture by rapidly moving back and forth across the flooded ditch. The submerged animal then emerged onto land revealing itself as an adult *L. catesbeianus*. We proceeded to track the frog over land, by sight and telemetry, through thick multi-flora roses until it disappeared into a large animal burrow. We tracked the radio signal back to the frog the next day, but our attempts to capture the animal proved unsuccessful. We were unable to pick up the radio signal the following day due to presumed exhaustion of the transmitter's battery. The radio transmitter included a thin vinyl coated antenna measuring ca. 9 cm long. The antenna was not observed protruding from the mouth of the frog and it is uncertain what effect it may have ultimately had on the predator. Although *L. catesbeianus* is known to consume nearly any animal it can fit into its mouth, this is believed to be the first report of *E. blandingii* having been consumed by this voracious and often abundant species.

EMYDOIDEA BLANDINGII (Blanding's Turtle). **HATCHLING DIET.** The behavior of hatchling *Emydoidea blandingii* in the wild is poorly understood. Previous studies have focused on the movements and habitat use of hatchlings after nest emergence (Butler and Graham 1995. Chelon. Conserv. Biol. 1:187–196; McNeil et al. 2000. Chelon. Conserv. Biol. 3:661–664). Herein, we report an observation of feeding behavior by a hatchling *E. blandingii* during its first weeks post emergence from the nest.

On 18 September 2007, six hatchling *E. blandingii* emerged from a protected nest at Winous Point Marsh, Ottawa Co., Ohio, USA. We attached radio transmitters to the hatchlings and released them at the nest site the same day. We tracked the hatchlings daily and GPS points were taken at each location. One hatchling tracked over the course of 29 days moved an average of 20 m/day. During this time it spent three days in a shallow, muddy agricultural ditch. The animal then exited this ditch and moved a short distance to a small vernal pool where it spent another three days along the shallow margins. The ditch and vernal pool were both located along a narrow strip of shrubby, wooded land between two agricultural fields.

On 15 October we tracked this individual to the top of a dike adjacent to the vernal pool. The animal appeared lethargic and did not move again. We found it dead and intact in the same location two days later. No obvious indication of the cause of death was observed, but a tear in the skin was noted anterior to the left front leg where fly eggs had recently been deposited. Dissection of the digestive tract of this animal revealed the chitinous remains of a small adult dytiscid beetle located within the colon along with some other unidentified material. The remains of the beetle measured ca. 5 mm long when articulated. The stomach contained an unidentified pink gelatinous material. Small perforations were observed in the wall of the stomach which were not believed to be due to researcher handling. The cause of these perforations and whether they resulted in the death of this animal could not be determined with certainty. However, it seems possible that they were associated with the death of this animal and may have occurred during consumption of the observed food item. Two additional hatchlings salvaged after predation and partial consumption (in 2006 and 2007) were also dissected and material was observed within the colon of each individual. The stomach was missing from both individuals and was presumably removed when the head of each had been consumed during predation. The colonic material included small bits of vegetation, grains of sand, and some unidentifiable material. Specimens will be deposited at The Cleveland Museum of Natural History.

Observations of narrow growth annuli on juvenile *E. blandingii* have previously hinted at hatchling feeding activity (Pappas et al. 2000. Chelon. Conserv. Biol. 3:557–568), but this is believed to be the first confirmation of post-emergence feeding activity by hatchling *E. blandingii* prior to their first winter dormancy.

GLYPTEMYS INSCULPTA (Wood Turtle). **ECTOPARASITES.** Although freshwater turtles are known to be parasitized with leeches of the genus *Placobdella* (e.g., Watermolen 1996. J. Fresh. Ecol. 11:211–217), several families of biting flies (Diptera) are ectoparasites of turtles as well. For example, biting midges in the genus *Culicoides* (Diptera: Ceratopogonidae) are well-known pests of vertebrates, including humans. Females of most *Culicoides* species require blood meals in order to produce one or more clutches of eggs [Blanton and Wirth 1979. Sand Flies (*Culicoides*) of Florida (Diptera: Ceratopogonidae), (in) Arthropods of Florida & Neighboring Land Areas. 10. 204 pp]. Currently, there are some 1300 known species of *Culicoides* [Borkent and Wirth 1997. World Species of Biting Midges (Diptera: Ceratopogonidae). Bull. Amer. Mus. Nat. Hist. 233:1–237.]. However, only one of the 152 Nearctic species (*Culicoides testudinalis*) is known to obtain blood meals from turtles. Herein, we report eight instances of *C. testudinalis* parasitizing the semi-aquatic turtle, *Glyptemys insculpta* in June of 2003 and 2004.

On 5 June 2003 at 0835, one of us (JM) observed two adult male *G. insculpta* (# 138 and # 1009) feeding on an unidentified species of slug, within 4 m of each other, at an undisclosed study site in Nova Scotia, Canada. Both of these turtles were noted to have many midges on their carapaces. Later, at 1110, an adult female *G. insculpta* (# 1011) that was covered with hundreds of small midges on its carapace, head, and limbs was observed and photographed (Figs. 1–2). At 1151, another adult female (# 1012) was found to be parasitized as well. On 17 June 2003 at 1230, an adult female (# 1113) was noted to have 13 midges; all but three were swollen with blood meals. On 19 June 2003 at 1125, another adult female (# NT39) was reported to be parasitized by midges, but no additional details were recorded.

Two additional observations were made in 2004. On 16 June 2004 at 0905, an adult female (#1194) was noted to have hundreds

of midges, many of which were on the carapace engorged with blood . Several midges were feeding upon the tissues surrounding the eyes as well. A final adult female (# 1177) was observed to be parasitized on 17 June 2004 at 0945. Although approximately 10 midges were associated with this *G. insculpta*, only one was engorged with blood. The mean carapace length (range) of the aforementioned eight *G. insculpta* was 195 mm (183–213 mm). The estimated minimum age of these turtles, based on carapacial growth annuli, ranged from 20–26 years.

Several dozen of the midges from one *G. insculpta* (# 1011) were collected and subsequently sent to WLG for identification. Nine unengorged midges were cleared in phenol-alcohol and mounted on microscope slides in phenol-Canada balsam by the methods of Wirth and Marston (1968. Ann. Entomol. Soc. Amer. 61: 783–784). Voucher specimens of slide-mounted *C. testudinalis* will be deposited in the Canadian National Collection of Insects (Ottawa, Ontario) and Florida State Collection of Insects (Gainesville, Florida). All slide-mounted midges are identical to three other females that were collected, mounted, and identified as *C. testudinalis* by Wirth; a paratype from Falls Church, Fairfax Co., VA, and two others from Prince Georges and Montgomery counties, Maryland in the synoptic collection of ceratopogonids maintained by WLG. The female holotype of *C. testudinalis* was collected on 6 June 1953 by Neill Richmond while it fed upon a Wood Turtle (*G. insculpta*) in Coburn, Centre County, Pennsylvania (Wirth and Hubert. 1962. Ann. Entomol. Soc. Amer. 55:182–195). Of the 78 female paratypes of this ectoparasitic midge, two were found biting *Terrapene carolina* at Patuxent Wildlife Refuge, Prince Georges County, Maryland by John Scanlon on 12 July 1958; whereas, three others were found "feeding on turtle" by R.C. Shannon on 23 May 1939 at Dead Run, Fairfax County, Virginia.

Notably, of the several hundred *C. testudinalis* observed on the turtles, most individuals appeared to have pierced the sulci between carapacial scutes or the margins of growth annuli with their fine-toothed mandibles in order to reach capillaries with their tubular mouthparts. This is consistent with observations of the biting midge *Leptoconops bezzii* feeding on the sulci between the scutes of

FIG. 1. Posterior portion of adult Wood Turtle (*Glyptemys insculpta*) infested with female biting midges (*Culicoides testudinalis*). Note that most of the midges are feeding in the sulci of successive scute layers and several engorged midges are resting on vegetation.

FIG. 2. Adult Wood Turtle (*Glyptemys insculpta*) from Fig. 1 infested with hundreds of adult female biting midges (*Culicoides testudinalis*) on its carapace, head, neck, and front leg. The swollen, reddish abdomens of some midges are engorged with blood from the turtle.

Testudo graeca in western Syria and Lebanon (Široký et al. 2007. Parasitol. Res. 101:485–489). Moreover, the leech, *Placobdella ornata*, is also known to obtain blood from the sulci between the scutes that overly the carapace bones (Siddall and Gaffney 2004. J. Parasitol. 90:1186–1188). Approximately 100 midges on one *G. insculpta* (# 1011) appeared to be fully engorged with blood, and a few that had completed feeding were resting on vegetation (Fig. 1). The highest densities of midges occurred between marginal and costal scute interfaces (Fig. 1); however, a much greater proportion of the midges on the anterior portion of the carapace were engorged (Fig. 2). Midges might initially be attracted to the head of a turtle, the source of exhaled CO_2. It is unknown if turtles suffer significant ill effects from the bites of *Culicoides*, but the *G. insculpta* in question were not observed attempting to dislodge any midges with forelimbs or engaged in any other erratic movements.

GLYPTEMYS MUHLENBERGII (Bog Turtle). **LONGEVITY.** Between May 1969 and June 1982, William Kimmich conducted mark recapture surveys of Bog and Spotted Turtles (*Clemmys guttata*) at several sites in southeastern Pennsylvania to gain information about population dynamics of these turtles. (The northern populations of the Bog Turtle were listed as a Threatened species by the U.S. Fish and Wildlife Service in November 1997.) During

this time period Kimmich marked approximately 100 Bog Turtles with small drill holes in the marginal scutes at one of these sites. Kimmich worked independently on this study, but provided his data and volunteer services to The Nature Conservancy after it acquired this property in 1989. Carl Ernst conducted research on Bog Turtles at this site between May 1982 and May 1989 and marked several additional Bog Turtles with square and triangular notches. Ernst also contributed data to the Conservancy for this analysis. In 1992 the Nature Conservancy, using staff and contractors, reinitiated mark/recapture surveys and conducted a short radio telemetry study at the site in 1992. Turtles marked during and after 1992 were marked exclusively with triangular notches in the marginal scutes. Turtles were sexed, and measurements of the carapace length and width, plastron length and width, and shell height were recorded. Shell wear and injuries were also noted at subsequent captures. These characteristics, as well as the configuration of markings on the marginal scutes, were used for the data comparison. At least 29 turtles (9 males and 20 females) that were marked as adults prior to 1982 were recaptured after 1992. Positive identification of some of these turtles has not been made because of erosion of holes to the edges of the scutes, the possible addition of marks to some turtles, predator damage to the marginal scutes, and drill holes filling with mud, making their detection difficult. Fourteen turtles were confirmed to be positive matches between the two data sets. Three of these turtles were recaptured in 1993, 1994 and 1997 respectively, and eleven of these turtles were recaptured after 2000. The most recent of these captures was made during the 2008 field season.

The average annual growth rate of Bog Turtles is rapid during the first years after hatching, and gradually decreases as the turtle ages. Ernst (1977. Herpetologica 33: 241-246) documented annual growth rates of 34.6 percent at hatchling with a gradual decline to 5.2 percent at age twelve, indicating that Bog Turtles reach their maximum size at some time after age 12. Comparison of Kimmich's data and that collected by The Nature Conservancy reveals an average size variation of 0.56 mm between initial and subsequent captures, indicating that these turtles were fully grown adults when first captured, and were presumed to be at least thirteen years old at first capture. Counting the number of scute annuli appears to be a reasonable method of determining approximate ages of Bog Turtles up to about 10 to 15 years, after which time growth may nearly cease and their burrowing habit will begin to wear away the annuli. While young Bog Turtles have distinct annuli, the annuli on the shells of turtles that were calculated to be more than 40 years old had been worn completely smooth. The earlier data did not note annuli count or wear and it is possible that several of these turtles are considerably older than the calculated ages. Many factors influence the speed and amount of wear on the shell, and shell wear may vary greatly between sites.

The ages of turtles in these studies were estimated using the aforementioned criteria. One turtle is estimated to be at least 25 years old, two turtles to be at least 35 years old, seven turtles to be at least 38 years old, three turtles to be at least 45 years old, and one turtle is estimated to be at least 49 years old. Notably, one female whose age is calculated to be more than 48 years old had all toes missing on both left feet at both captures, and thus had survived for at least 35 years in the wild in this condition.

GOPHERUS AGASSIZII (Desert Tortoise). **MORTALITY.** In 1990, populations of *Gopherus agassizii* in the Mojave Desert were listed as Threatened under the US Endangered Species Act (Fish and Wildlife Service 1990. Federal Register 55:12178–12191). This action was deemed necessary because of the increase in habitat loss and degradation in the Mojave Desert due to the rapid growth of many cities and suburban communities (Boarman and Beaman 2002. The Sensitive Plant and Animal Species of the Western Mojave Desert. U.S. Geological Survey, Western Ecological Research Center, Sacramento, California). Although anthropogenic activities undoubtedly contribute to *G. agassizii* mortality, many natural causes of mortality have also been reported. Many of the natural dangers to *G. agassizii* appear to affect young tortoises more than older individuals. Among the many threats are predation, parasites, disease, dehydration, and being crushed when dens collapse (Luckenbach 1982. *In* R. B. Bury [ed.], North American Tortoises: Conservation and Ecology, pp. 1–37. Wildl. Res. Rep. 12, U.S. Fish and Wildlife Service, Washington, DC). Here we report the first observations of *G. agassizii* mortality caused by individuals falling into and being trapped in rock fractures on a basalt flow.

The habitats where *G. agassizii* can be found in the Mojave Desert vary from sandy valleys filled with Creosote Bush (*Larrea tridentata*), to rocky bajadas and hillsides (Riedle et al. 2008. Copeia 2008:414–420). Studies of *G. agassizii* in the Sonoran Desert suggest that preferred den sites may occur in rugged terrain with high densities of boulders (Barrett 1990. Herpetologica 46:202–206). Several reserves have been established with the aim of protecting critical tortoise habitat. The Red Cliffs Desert Reserve, Washington Co., Utah, was established in 1996 to protect a large tract of desert habitat suitable for *G. agassizii* and other desert wildlife. This reserve contains a diverse suite of habitats, from Blackbrush (*Coleogyne ramosissima*) covered mesas, to sandstone and basalt rock outcrops, to creosote bush flats.

On two occasions on separate basalt flows in the Red Cliffs Desert Reserve, carcasses of adult *G. agassizii* were found. These individuals had apparently fallen headfirst into fractures in the rocks, become stuck, and died from exposure, likely from overheating. Both individuals had their hind legs in the air and their forelegs and head dangling down into the crack. No noticeable marks were found on the tortoise carcasses that would suggest they were killed and placed in the cracks by predators. It is unknown what caused the tortoises to wander onto the basalt flows.

This finding is interesting because tortoises in the Red Cliffs Desert Reserve often traverse steep sandstone outcrops with little difficulty (pers. obs.). It is likely a rare event for a tortoise to be trapped by falling into a crack in the rocks, yet given that two individuals were trapped and died in a similar manner, this may be a more common event than previously thought.

HYDROMEDUSA MAXIMILIANI (Brazilian Snake-necked Turtle). **ALGAL COLONIZATION.** Algae of the genus *Basicladia* (Chlorophyta, Cladophoraceae) are often noted growing on the shells of freshwater turtles, which offer the algae an attractive substrate for colonization (Edgren et al. 1953. Ecology 34:733–740; Ducker 1958. Hydrobiology 10:157–174; Semir et al. 1988. Cienc. cult. 40:885–888). The relationship between algae and turtles has been described as commensal (assuming the turtles receive little or no benefit from the algae) or mutualistic (the turtle using the algae as camouflage, perhaps while foraging, and the algae using the turtle as a safe and mobile substrate) (Edgren et al., *op. cit*.; Niel and Allen 1954. Ecology 35:581–584; Proctor 1958. Ecology, 39:634–645; Dixon 1960. Texas J. Sci. 12:36–38).

In November 2004 we captured seven *Hydromedusa maximiliani* in Reserva Biológica Municipal Santa Cândida (21.6888889°S, 43.3444444°W, 770 m elev.), Juiz de Fora, Minas Gerais state, Brazil. Algae on the turtle's shells were collected with a scalpel and fixed in Transeau and formaline 4% solution. Biometric analysis suggested that six of these specimens were adults, with an average maximum carapace length of 150.60 ± 12.51 mm, and one was considered a juvenile, with a carapace length of 128.60 mm. All specimens had *B.* cf. *chelonum* adhering to their carapaces, on the vertebral plates, principally on the anterior and posterior regions, and on the marginal plates. The same distribution of algae was also noted for the chelids *Phrynops geoffroanus* and *Hydromedusa tectifera* from Brazil (Semir et al. 1988. Cienc. Cult. 40:885–888). The algae occurred mainly in the anterior and posterior regions of the carapace on the marginal scutes, there being little algae on the costal and central scutes.

A possible correlation between the feeding habits of turtles and frequency of epizoophyte growth is supported by the observation that carnivorous species that ambush or actively hunt their food may be more often subject to algal growth. Examples include include the chelydrids *Macrochelys* and *Chelydra*, kinosternids *Sternotherus* and *Kinosternon*, and the emydids *Deirochelys* and *Emys*. all of which hunt active prey, such as frogs, fish and aquatic insects (Niel and Allen 1954. Ecology 35:581–584). *H. maximiliani* has similar predatory feeding habits (Souza and Abe 1995. Chel. Cons. Biol. 1:320–322). The presence of algae on the carapace of this species may serve as protection against predators but would also decrease detection by prey. This record of *B.* cf. *chelonum* colonizing *H. maximiliani* is apparently the first report of the algae growing on this turtle species and supports a possible mutualistic relationship between the algae and the turtle host.

MACROCHELYS TEMMINCKII (Alligator Snapping Turtle). **AERIAL BASKING.** *Macrochelys temminckii* is rarely observed out of the water. Terrestrial activity is typically limited to nesting females and hatchlings traveling from nest to water. Only two dead-on- road individuals are known (Ewert et al. 2006. *In* Meylan [ed.], Biology and Conservation of Florida Turtles, pp. 58–71. Chelon. Res. Monogr. No. 3, 376 pp.). Apparently, only four instances of observed or inferred aerial basking have been reported: on a log in Texas (Ewert 1976. Herpetologica 32:150–156; also see Ewert et al., *op. cit*.), on a fallen tree in Texas (Farr et al. 2005. Herpetol, Rev. 36:168), on a basking trap in Mississippi (Shelby and Jenson 2002. Herpetol. Rev. 33:304), and an adult basking on a river bank, also in Mississippi (Selman et al. 2009. Herpetol. Rev. 40:79). Here I report aerial basking of *M. temminckii* on land in Florida.

The observation was made as part of a long-term (since 2003) ecological study of *Macrochelys temminckii* in northern peninsular Florida. On 19 October 2008 at 1300 h, I found a juvenile (18.6 cm CL, 1.68 kg) *M. temminckii* on the northern bank of the Santa Fe River, Columbia Co. Florida, 1.7 km upstream from the US 27 bridge. This turtle was basking in partial sunlight at least 2 m from the water's edge. The turtle was found on sandy soil and appeared completely dry. Air temperature and water temperature (10 cm depth) were 23.3 and 22.5°C, respectively. Upon capture, this turtle was found to have been originally marked with a passive integrated transponder (PIT) on 9 July 2008, and had traveled ca. 2.5 km from the initial capture site. Additionally, I counted over 100 leeches that were attached to the turtle. This is the first report of aerial basking in Florida. Aerial basking in this species is certainly rare, but may occur sporadically in response to thermoregulatory needs of individual turtles.

PHRYNOPS HILARII (Hilaire's Side-necked Turtle). **FEEDING BEHAVIOR.** The freshwater chelid turtle *Phrynops hilarii* is one of the most abundant chelonians in Rio Grande do Sul state, Brazil. Research by the Chelonia-RS Project in the lake at Moinhos de Vento Park, Porto Alegre city (30.0269444°S, 51.2011111°W) has been carried out intermittently since 2003. Between August and December 2008, 29 *P. hilarii* were captured and marked. Straight-line carapace length ranged between 113 and 387.2 mm (mean = 280.21; SD = 81.2). In the lake, which is ca. 4675 m^2 in area and has a maximum depth of 1.5 m, there are four other chelonian

species (*Trachemys dorbigni*, *T. scripta*, *Acanthochelys spixii*, and *Hydromedusa tectifera*). This note provides additional data about the diet and feeding behavior of *P. hilarii* at this location.

Predation of waterfowl and other birds by chelonians has been reported for the Snapping Turtles, *Chelydra serpentina*, and the Red-eared Slider, *Trachemys scripta elegans* (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Inst. Press, Washington, D.C.; Ligon 2007. Herpetol. Rev. 38:201–202; Pryor 1996. Wilson Bull. 108:190–192). However, predation of non-aquatic birds by *P. hilarii* has not been previously described.

Pigeons (*Columba livia*) are abundant in the park and capture of the species by *P. hilarii* was observed by Daniel Borba Rocha and co-workers in 2004. On 9 October 2007, I described (field notes of the Chelonia-RS Project) the predation of a pigeon by a *P. hilarii* while the bird was drinking water at the margin of the lake. The turtle, without leaving the water, grabbed the bird by the neck with its jaws, and pulled it to the bottom of the lake, while other turtles (*T. scripta* and *P. hilarii*), also bit at the bird. On 22 January 2009, pictures and a report about pigeon predation by the Hilaire's Side-necked Turtle were published in a local newspaper (Zero Hora newspaper 2009. 15849:42). In this situation, the capture occurred on land as pigeons foraging on the margins of the lake were ambushed by a *P. hilarii*. When the birds got close to the margin of the lake, the turtle left the water and quickly attacked one of the birds (Fig 1A). The prey, at different times, was captured by the legs (Fig. 1B, C) or by the base of the neck (Fig. 1D). After the capture, the turtle brought the prey into the water and submerged with it (Fig. 1E). In the water, other turtles, presumably attracted by the movement and by the chance of obtaining food, also attacked the prey (Fig. 1F, G). A video showing what was reported here is available at http://csbujes.blogspot.com/.

FIG. 1. Sequence of predation by Hilaire's Side-necked Turtle on pigeons in Moinhos de Vento Park, Porto Alegre City, Rio Grande do Sul, Brazil.

The predation of small aquatic birds by turtles is apparently occasional, and/or opportunistic in nature, however, the behavior of leaving water displayed by *P. hilarri* suggests an intentional act of capture not previously described.

I thank the photographer of Zero Hora, Ronaldo Bernardi, for making photographic material and videos available. Thanks to the administration of the Moinhos de Vento Park; to the biologist Soraya Ribeiro; to the wildlife management group of the Secretaria de Meio Ambiente de Porto Alegre; and to the researchers in the Chelonia-RS Project of the Departamento de Zoologia da Universidade Federal do Rio Grande do Sul.

PSEUDEMYS RUBRIVENTRIS (Northern Red-bellied Cooter). **HATCHLING BEHAVIOR.** We observed the locomotion and behavior of hatchling *Pseudemys rubriventris* that emerged and departed from a nest at Jug Bay Wetland Sanctuary, Anne Arundel County, Maryland, USA (38.7858333°N, 76.7136111°W). At Jug Bay, Red-bellied Cooters nest in open, sunny areas 100–225 m from a large freshwater tidal wetland bordering the Patuxent River (Swarth 2004. *In* Swarth et al. [eds.], Conservation and Ecology of Turtles of the Mid-Atlantic Region, pp. 73–84. Bibliomania!, Salt Lake City, Utah). Turtle hatchlings often disperse quickly from the nest and may move directly to water or to dense vegetation or under leaves where they are difficult to observe. Tuttle and Carroll (2005. Northeast. Nat. 12:331–348) tracked hatchling Wood Turtles (*Glyptemys insculpta*) as they moved from nests to water in New Hampshire; researchers in New Jersey found that hatchling Wood Turtles did not travel directly to water, but remained in a field for days to weeks (Castellano et al. 2008. Chelon. Conserv. Biol. 7:113–118).

Here we describe the post-emergence movements and behavior of Red-bellied Cooter hatchlings under natural field conditions. The hatchlings under observation emerged from a nest discovered at 0900 h on 27 June 2007 when the female was observed laying eggs. The nest was immediately covered with a screened predator exclusion cage and was checked daily after 1 September 2007 to determine the date of hatchling emergence. The nest was in well-drained, sandy substrate next to a tractor shed, about 90 m from a large tidal wetland. The nest was partially shaded by the shed canopy roof and there was no vegetation within several meters.

Following a 98-day incubation period, eight hatchlings emerged from the nest at 1715 h on 3 October 2007. Air temperature was 27°C and there had been no rain for more than six days. The hatchlings were contained at the nest under the predator exclusion cage until the next morning. (Upon excavation, the nest held five dead,

under-developed hatchlings and three intact, unfertilized eggs).

On 4 October, we released four hatchlings at 1000 h and four at 1100 h. Air temperature during the observations varied from 21°C to 26°C. We glued a yellow, 10 cm long bristle in an upright position to the carapace of each hatchling to help us observe them as they moved through the grass. However, we removed the bristles when they became entangled in vegetation a short distance from the nest. We then affixed a thin, 10 cm long strip of colored plastic flagging to the rear of each shell. We observed the hatchlings from a distance of 25 m in order to minimize observer effect. We noted the hatchlings' rate of movement and behavior as they crossed the field heading for the shrub/sapling area where we lost sight of them in the leaf litter.

The terrain between the nest and the wetland consisted of 30 m of open mowed field; 30 m of level, shady shrub/sapling habitat with ample leaf litter; and 30 m of sloping forest-covered bluff extending downhill to the wetland. The hatchlings alternated between short bursts of rapid walking and periods of rest and concealment. As they walked across the 30 m of mowed field most of the hatchlings moved steadily for 5–10 min., then rested in taller grass clumps before moving on. Prior to reaching the forest edge, two of the hatchlings burrowed into the ground for several hours before moving on.

For six hatchlings, we measured path length, amount of time required to cover the distance from nest to forest edge, rate of movement, and maximum speed. All walking paths were N or NW away from the nest site directly toward the wetland. Mean path length across the mowed field for each of the six hatchlings walking from nest to forest was 29.7 m (SD = 6.8 m, range: 21.9–40.8 m). Mean travel time to cross the field was 134 min. (SD = 73 min., range: 40–244 min.). Mean rate of movement was 17.6 m/h (range 6.6–38.7 m/h). Maximum speed was 38.7 m/h.

For aquatic turtle species that deposit eggs in upland areas, hatchlings are quite vulnerable to predation as they move from the nest toward water. Hatchlings minimize this risk by moving quickly across exposed fields or lawns. Upon emergence, Red-bellied Cooter hatchlings in our study area generally leave the nest site immediately and invariably walk directly toward the tidal wetlands. However, predators may also be alerted to the movement of a rapidly walking hatchling. Hatchlings may minimize the risk of predation by alternating between bursts of relatively rapid movement followed by periods of rest where they are immobile. Additionally, the variability in the pattern of movement and stasis that we observed, wherein some hatchlings crossed the field quickly while others spent several hours making the journey, suggests that behavioral heterogeneity among nest mates might reduce predation risk.

Each hatchling under observation walked in almost the same direction towards the wetlands. It is possible that hatchlings move towards bright light from the sky that is visible on the horizon and avoid moving toward areas that are dark or shady. The sky was visible and bright at ground level through the trees and shrubs to the northwest of the nest. A sky that is visible through vegetation may be a cue to hatchlings that the terrain drops off towards lower elevations. By walking in this direction hatchlings would travel downhill, eventually reaching the safety of a stream, pond, or wetland.

Submitted by **RACHAEL DICKEY, SUSAN MATTHEWS,** and **CHRISTOPHER W. SWARTH,** Jug Bay Wetlands Sanctuary, 1361 Wrighton Rd., Lothian, Maryland 20711, USA (e-mail: Cswarth@jugbay.org).

TERRAPENE CAROLINA MAJOR (Gulf Coast Box Turtle). **SWIMMING**. With the exception of *Terrapene coahuila* (Cohuilan Box Turtle), members of the genus *Terrapene* have been considered to be primarily terrestrial (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press, Washington, D.C., pp. 250–265). The occasional use of aquatic habitats, perhaps for drinking or thermoregulation, is often noted (Bonin et al. 2006. Turtles of the World. John Hopkins Univ. Press, Baltimore, Maryland. 416 pp; Dodd 2001. North American Box Turtles: A Natural History. Univ. Oklahoma Press, Norman, Oklahoma. 231 pp.), but instances of actual swimming are less common (McCauley 1945. The Reptiles of Maryland and the District of Columbia. Privately printed, Hagerstown, Maryland. 194 pp.; Stickel 1950. Ecol. Monogr. 20:361; Tyler 1979. Southwest. Nat. 24:189–190; McDowell et al. 2004. Herpetol. Rev. 35:265–266). *Terrapene c. major* occupies coastal wetland or near-wetland habitats in the southeastern USA and will walk and forage on the bottoms of ponds and canals (Bartlett and Bartlett 1999. A Field Guide to Florida Reptiles and Amphibians. Gulf Publ., Houston, Texas. 280 pp.). Here we report a long-distance swimming event for this subspecies.

On 28 June 2008, at ca. 0900 h, we observed a male *T. c. major* swimming across the East Fowl River in Mobile Co., Alabama, USA. The turtle was sighted by boat in the center of the river, swimming in a northwesterly direction away from the south bank. The turtle was swimming at the surface with its head up and approximately two-thirds of its carapace above the water line. Upon approach, the turtle ceased swimming and began to float. We collected the turtle to verify the identification and sex. The turtle was photographed and then returned to the water. As we moved away, the turtle continued to swim towards the north bank. The width of the river at this location was measured, using ArcGIS, to be ca. 320 m. We observed the turtle for 15 minutes until it came within 20 m of the north bank, at which time we continued up the river.

Swimming and river crossings have been previously reported for subspecies of *T. carolina* (references, *op. cit.* from above), and *T. ornata* is capable of swimming (Richtsmeier et al. 2008. Chelon. Conserv. Biol. 7:3–11), but the distances reported for these events are generally short (< 20 m), and large rivers have been considered as possible barriers to dispersal and gene flow (Richtsmeier et al., *op. cit.*). In the instance described above, the circumstances resulting in this animal swimming such a long distance are unknown. However, the ability to swim across large bodies of water has implications for gene flow between populations that would otherwise be considered geographically isolated.

We thank James Lee, David H. Nelson, and Ashley B. Morris for their comments.

SQUAMATA — LIZARDS

AMEIVA AMEIVA (Green Lizard). **ATTEMPTED PREDATION OF AMPHISBAENIAN**. *Ameiva ameiva* (Teiidae) is a moderate-sized (to 190 mm SVL), terrestrial lizard that occurs in nearly all tropical habitats of South America (Pianka and Vitt 2003. Lizards: Windows to the Evolution of Diversity. University of California Press, Berkeley, California. 333 pp.). It is an active forager with a generalist diet that includes plants and vertebrates, though dominated by arthropods (Vitt and Colli 1994. Can. J. Zool. 72[11]:1986–2008).

On 19 October 2004 at 1438 h, in an area of Cerrado in the municipality of Bauru, São Paulo State, Brazil (22.340690°S 49.018190; datum: WGS84; elev. 580 m) we observed an adult *A. ameiva* (ca. 150 mm SVL) attacking a Spade-snouted Worm-Lizard (*Leposternon microcephalum*) ca. 300 mm total length (Fig. 1). During a period of 20 minutes, we observed the *Ameiva* repeatedly shake the *L. microcephalum* from side to side, occasionally releasing its grip and then biting again. Eventually, the *Ameiva* released the *L. microcephalum* and retreated to a hole in a shaded ravine. We examined the amphisbaenian and noted small bite marks but the skin was not torn; it seemed exhausted and moved slowly. The latter was collected and added to collection of the House of Reptiles of Bauru Zoo.

Records of predation of *L. microcephalum* include a coralsnake (*Micrurus corallinus*) and a mammal (*Nasua nasua*) (Marques and Sazima 1997. Herpetol. Nat. Hist. 5:88–93; Oliveira et al. 2004. Herpetol. Rev. 35:170–171). This is the first report of predation of *L. microcephalum* by *A. ameiva* and the first occurrence of predation by this species on an amphisbaenian.

ASPIDOSCELIS COSTATA (Western México Whiptail). **CANNIBALISM**. Cannibalism is common among reptiles (Mitchell 1986. SSAR Herpetol. Circ. No. 15, 37 pp.) and has been recorded in a number of lizard species (e.g., Castilla and Van Damme 1996. Copeia 1996:991–994; Moll and Koenig 2003. Sonoran Herpetologist. 16:90–91; Keren-Rotem et al. 2006. Behav. Ecol. Sociobiol. 59:723–731). The teiid genus *Aspidoscelis* includes insectivorous lizards (Anderson 1993. *In* Wright and Vitt [eds.], Biology of Whiptail Lizards (Genus *Cnemidophorus*), pp. 83–116. Oklahoma Mus. Nat. Hist., Norman; Vitt and Pianka 2004. *In* Pérez-Mellado et al. [eds.], The Biology of Lacertid Lizards, pp. 139–157. Evolutionary and Ecological Perspectives. Institut Menorquí d'Estudis, Recerca. Lesvos, Greece). Though the diet of *Aspidoscelis* spp. is often characterized as comprising mainly insects, some records exist of cannibalistic behavior, especially among temperate zone species (Etheridge and Wit 1982. Herpetol. Rev. 13:19; Mitchell 1979. Can. J. Zool. 57:1487–1499). However, as no reports of cannibalism exist for *A. costata*, we report an instance of cannibalism in this species.

On 18 October 2008 (rainy season), MAGR captured a juvenile male *A. costata* (60 mm SVL, 6.6 g) at Mezcala, Guerrero (17.9101°N, 99.6148°W, datum: WGS84; 548 m elev.) in southern México. Dominant vegetation is tropical dry forest with a wet season from July to October and a dry season from November to June. Examination of its stomach contents revealed a conspecific hatchling (35 mm SVL, 1.0 g). The hatchling had been swallowed headfirst and showed little evidence of digestion, indicating that it had been consumed just before the juvenile's capture. In short-lived animals such as small lizards, population dynamics appear to be particularly sensitive to fluctuations in annual recruitment and survival of eggs and juveniles (Castilla and Vand Damme 1996. Copeia 1996:991–994). In that sense, cannibalism of hatchlings could be a mechanism to reduce intraspecific competition or a form of population regulation (Fox 1975. Ann. Rev. Ecol. Syst. 6:87–106).

Both specimens (predator and prey) were deposited in Colección Nacional de Herpetología, Instituto de Biología, Universidad Nacional Autónoma de México (IBH 20202 and 20209, respectively).

ASPIDOSCELIS MARMORATA (Western Marbled Whiptail). **FACULTATIVE FRUGIVORY**. *Aspidoscelis marmorata* inhabits semiarid environments in southern New Mexico and Texas, and in northern México in Coahuila, Chihuahua, and

Durango (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin, Boston, Massachusetts. 533 pp.). Previous studies of stomach contents have shown that insects comprise most of the diet, and that some plant material may be taken in very low quantity (Gadsden and Palacios-Orona 2000. Acta Zool. Mex. 79:61–76; Lemos-Espinal and Smith 2007. Amphibians and Reptiles of the State of Coahuila, Mexico. UNAM and CONABIO. 550 pp.) but frugivory has not been documented. This is the first observation of intentional fruit ingestion in the species.

On 2 November 2004 around 1300 h, we observed an adult *A. marmorata* at Mapimí Biosphere Reserve in central Chihuahuan Desert, Durango, México (26.6662°N, 103.7471°W, WGS84, elev. 1150 m) consuming a fleshly, juicy, red fruit of *Opuntia leptocaulis* (Cactaceae). The lizard picked up the fruit from the ground in its mouth and consumed most of. *Opuntia leptocaulis* (Desert Christmas Cholla) occurs throughout the Chihuahuan Desert. Their fleshy, highly attractive fruits are common and ripen during winter, and are frequently consumed by a variety of vertebrates, especially birds and small mammals (Goettsch and Hernández 2006. J. Arid Environ. 65:513–528).

In xeric habitats, food availability is frequently unpredictable and scarce, so opportunistic feeding could shape the diets of many lizard species (Whiting and Greeff 1997. Copeia 1997:811–818). Fruiting *O. leptocaulis* are food resources that are widely available in late fall. Fruit consumption by *Aspidoscelis* lizards could be an interesting issue for the study of facultative frugivory.

ASPIDOSCELIS TESSELATA (Checkered Whiptail) × ***ASPIDOSCELIS SEXLINEATA VIRIDIS*** (Prairie Racerunner). **REPRODUCTIVE POTENTIAL**. Pattern class E (Zweifel 1965. Am. Mus. Novit. 2235:1–35) of diploid (Lowe et al. 1970. Syst. Zool. 19:114–127) parthenogenetic *Aspidoscelis tesselata* (*sensu* Reeder et al. 2002. Am. Mus. Novit. 3365:1–61), derived from hybridization between *A. marmorata* (= *tigris*) *marmorata* × *A. gularis septemvittata* (Parker and Selander 1976. Genetics 40:245–252; Cordes and Walker 2006. Copeia 2006:14–26), is syntopic with gonochoristic *A. sexlineatus viridis* and parthenogenetic *A. neomexicana* near the railroad depot in the city of Fort Sumner, De Baca Co., New Mexico, USA (34.47389°N, 104.23944°W; datum: WGS84; elev. 1250 m). On 12 July 2002, GJM collected a male lizard (University of Arkansas Department of Zoology, UADZ 7619) at this site possessing characters of scutellation and components of the dorsal and ventral color patterns that appeared to be phenotypically derived from hybridization between *A. tesselata* and *A. sexlineata viridis*. Analyses of morphological characters in the apparent hybrid and samples of the putative parental species from Fort Sumner (Manning and Walker 2006. Am. Midl. Nat. 2006. 155:411–416) confirmed that UADZ 7619 resulted from a haploid sperm of *A. sexlineata viridis* (1n = 23) fertilizing an unreduced egg of *A. tesselata* (2n = 46). Though this is the first reported example of this hybrid combination, *A. tesselata* E (= pattern class EC of Taylor et al. 2003. Am. Mus. Novit. 3424:1–40) has been identified as a participant in frequent hybridizations with its maternal progenitor *A. marmorata marmorata* at a site in New Mexico (Taylor at al. 2001. Am. Mus. Novit. 3345:1–65).

Based on Walker et al. (1989. Copeia 1989:1059–1064; 2006. Herpetol. Rev. 37:344–345) and Taylor et al. (2001, *op. cit.*), JMW described the gross reproductive morphology of the preserved hybrid (UADZ 7619). Based on Goldberg and Beaman (2003. Herpetol. Rev. 34:143), SRG histologically examined the left testis and left epididymis of the hybrid and assessed its previous reproductive functionality.

The hybrid was 70 mm in SVL. Compared to males of *A. sexlineata viridis* of similar size from Fort Sumner, its testes (mean dimensions of both = ca. 3.8 × 6 mm), epididymides, and hemipenes were of expected size and structure. Histology of the left testis indicated that UADZ 7619 was undergoing early spermiogenesis when collected. As reported for other teiid lizards (Lowe and Goldberg 1966. J. Morphol. 119:277–281); a circumtesticular tunic 1–3 Leydig cells thick surrounded the left testis. Clusters of metamorphosing spermatids were present and tails of spermatozoa projected into the lumina of the seminiferous tubules. Sperm were also present in the sectioned epididymis.

This *A. tesselata* × *A. sexlineata viridis* hybrid would have been deemed fertile based on cytological characteristics of testes in species such as *A. tigris* (Lowe and Goldberg, *op. cit.*). However, though it seemed capable of producing sperm and inseminating females of *A. tesselata*, *A. neomexicana*, and *A. sexlineata viridis* at Fort Sumner, its ability to produce a stable haploid chromosome complement from a triploid number of 69 is dubious. Nevertheless, the hybrid likely would have interfered with normal reproduction in some females of these three species should any of them have been inseminated. Taylor et al. (2001, *op. cit.*) provided morphological and histological descriptions of gonads and ducts of both male and female hybrids of *A. tesselata* × *A. marmorata* collected at Macho Draw, Chaves Co., New Mexico, and provided indirect evidence that some hybrid males (N = 12) may have inseminated congeneric females at this site.

Collection of UADZ 7619 was made under authority of Permit No. 3118 issued to GJM in 2002 by the New Mexico Department of Game and Fish.

CALOTES "VERSICOLOR" (Burmese Garden Lizard). **GLIDING**. During surveys of the Burmese herpetofauna (NSF DEB-9971861, DEB-0451832), we periodically sampled the components

of the Hlawga Wildlife Park fauna (17.043°N, 96.1271667°E; Yangon Division, Myanmar). On 28 February 2009, we focused on the lizard *C. "versicolor"* (Quotes indicate the population is a member of this species group; true *C. versicolor* does not occur in Myanmar.), and discovered that members of the Hlawga population glide. Hlawga *C. "versicolor"* are wary and typically take evasive action when a person approaches within 4–5 m of "their" tree. These lizards are sit-and-wait predators, and typically cling to the sides of trees, usually 1–2 m from the tree base. When a potential predator approaches, evasive action begins with a slight upward movement around the tree, apparently in an effort to escape detection. If pursued, even slowly, they continue to circle the tree trunk, constantly moving upward. Our observation concerns an adult on a tree isolated in a grassy patch. As we approached, the lizard immediately climbed to nearly 3 m. Being the dry season, the tree was leafless. A park ranger decided to aid capture by climbing the tree. The lizard continued to the top (about 12 m); at about 10 m, the tree was too slender for the ranger to reach the lizard, so he chopped off the tree top and moved slowly and held the top horizontal. We expected the lizard to simply drop directly downward; instead it leaped outward and descended at roughly 45°, landing in a brush pile and eluding capture. The descent angle alone does not imply gliding, but in association with the lizard's deliberate vertical outward leap and its posture of straight body and head with outstretched fore- and hindlimbs, dorsoventrally flattened trunk, and tail held straight backward (rigidly so, i.e., no movement), the controlled descent can be defined as gliding behavior.

Gliding is certainly not an unknown agamid behavior owing to the spectacular gliding performance of the various species of *Draco*, but it has not been reported in other agamid taxa except *Bronchocela cristatella* (Allen 1957. Malayan Nat. J. 11:81; Reid 1958. Malayan Nat. J. 12:119). Both of these reports note that the lizard was observed to leap outward and descent vertically from its origin at a roughly 40–45° angle. We suggest that these and other species of lighter-bodied arboreal agamids may use this mode of escape, but that it would be rarely seen and uncommonly used because these lizards are often successful at eluding capture by climbing, hiding, or jumping short distances to other trees.

CELESTUS CURTISSI (Curtis' Galliwasp). **REPRODUCTION.** *Celestus curtissi* is restricted to Hispaniola where it is known from Haiti and the Dominican Republic (Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies. Descriptions, Distributions, and Natural History. Univ. Florida Press, Gainesville. 720 pp.). It is ovoviviparous with brood sizes of 2–5 (Schwartz and Henderson 1991, *op. cit.*). The purpose of this note is to report a new minimum brood size for *C. curtissi*.

Two female *C. curtissi* from the Dominican Republic collected August 1976, were examined from the herpetology collection of the Natural History Museum of Los Angeles County (LACM). Both (LACM 125351, SVL 63 mm; LACM 125354, SVL 64 mm) were from Pedernales Province, 5 km NE of Oviedo (17.7833°N, 71.3666°W, datum: WGS 84; elev. 3 m).

A mid-ventral incision was made in the lower abdomen and the ovaries were examined. One well-developed embryo was observed in LACM 125354 and one oviductal egg was in LACM 125351. Ober (1970. Herpetol. 26:275) reported one *C.* (as *Diploglossus*) *curtissi* gave birth to five young in September. One embryo represents a new minimum brood size for *C. curtissi*.

I thank Christine Thacker (LACM) for permission to examine *C. curtissi*.

CYCLURA CYCHLURA INORNATA (Allen Cays Rock Iguana). **CAUSE OF MORTALITY**. Jetsam, flotsam, and other discarded material has been shown to be a source of mortality for reptiles (e.g., Laist 1997. *In* Coe and Rogers [eds.], Marine Debris: Sources, Impacts, and Solutions, pp. 99–139. Springer-Verlag, New York; Benedict and Billeter 2004. Southeast. Nat. 3:371–377; Mascarenhas et al. 2004. Mar. Poll. Bull. 49:354–355). We report on jetsam-related sources of mortality for the *Cyclura cychlura inornata*.

The Allen Cays Rock Iguana is a CITES-listed species restricted to a few small cays in the Exuma Islands of the Bahamas (Iverson et al. 2005. Cat. Amer. Amphib. Rept. 810:1–9). It has few, if any, natural predators as adults, and relatively high adult and juvenile survivorship (Iverson et al. 2006. Biol. Conserv. 132:300–310; Iverson 2007. Copeia 2007:740–744). Documented sources of mortality include accidental death (Iverson et al. 2005. Herpetol. Rev. 36:175), and there is some concern about the possibility of poaching or other human- or tourism-related stressors (Iverson et al. 2006. Biol. Conserv. 132:300–310; Smith and Iverson 2006. Can. J. Zool. 84:1522–1527). We observed another possible cause of mortality related to oceanic refuse of jetsam causing the death of four juvenile Allen Cays Iguanas.

On 15 May 2008, three juvenile iguanas were found dead inside a large 50-gallon (189 liter) plastic drum on a cay near the Allen Cays (exact location not provided for conservation purposes). The drum had apparently washed up on the coastline, probably within the previous year. There were two small openings on the top of the drum through which the juveniles apparently entered (Fig. 1A). All three iguanas were about the same size (SVL ≈ 14 cm, 20 cm, 21 cm) and at a similar state of decomposition (Figs. 1B, 1C), suggesting that they may have been using the drum as a communal retreat until wind or waves reoriented the drum and prevented the lizards' escape. The three iguanas were all clearly juveniles based upon their size (Fig. 1C).

One juvenile iguana was found dead in a small upright freezer half filled with rain water on Southwest Allen's Cay (U Cay) (24.75°N, 76.84°W; see Iverson et al. 2004. Herpetol. Monogr.

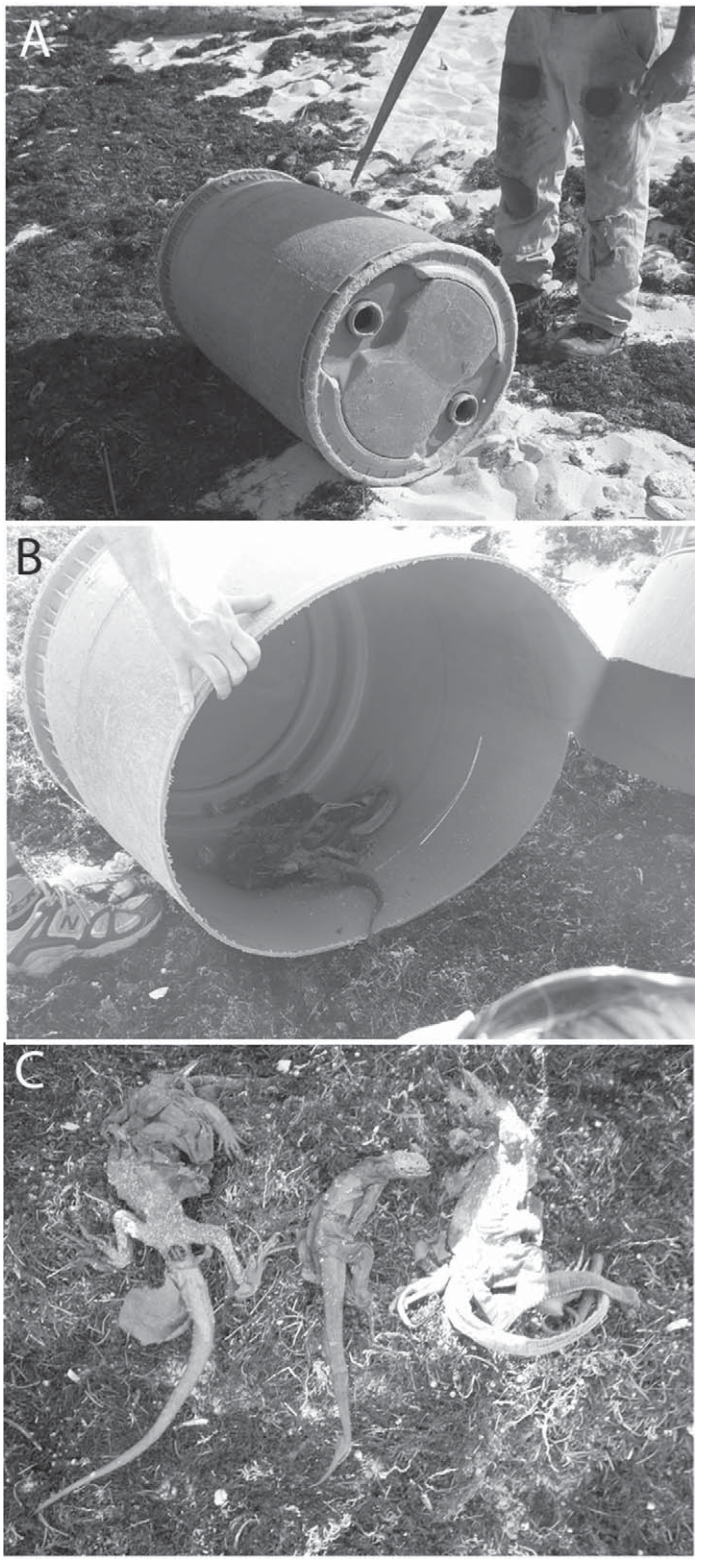

FIG. 1. A) The 50-gallon barrel as originally discovered; B) the remains of the three juvenile Allen Cays Iguana (*Cyclura cychlura inornata*) as found inside the barrel; and C) the remains of the three iguanas after removal from the barrel. Photos by Kirsten Hines (A), Lynne Pieper (B), and Stesha Pasachnik (C).

18:1–36 for a detailed description) on 16 May 2008 (Fig. 2A). The iguana had apparently fallen into the water and drowned. Few remains were found, but based on their size, it is highly probable

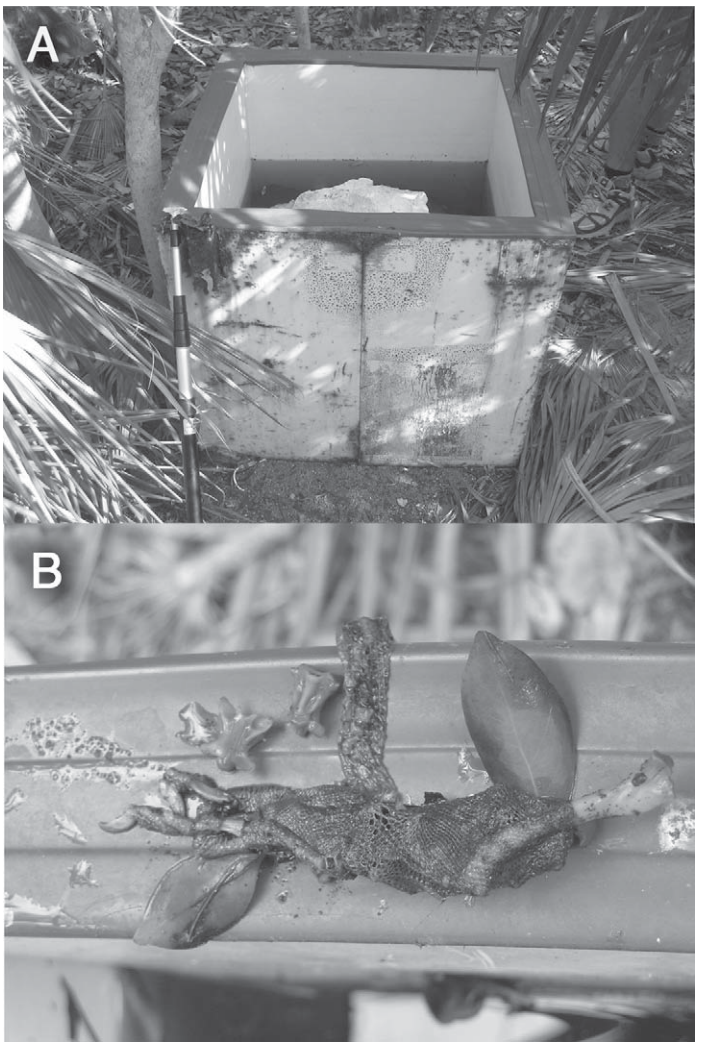

FIG. 2. A) The upright freezer partially filled with rain water; and B) the remains of one juvenile Allen Cays Iguana (*Cyclura cychlura inornata*) found in the water inside the freezer. Photos by Lynne Pieper.

that the individual was a juvenile (Fig. 2B).

Although the mortality events that we observed are likely rare, it does suggest that material washing up on the shores of these small cays can be an additional source of mortality, especially for smaller and younger iguanas, and potentially other native wildlife.

We thank Bruce Dunham and Will McLean of the M/V Bahama Star for help opening the barrel. Funding for this project was provided by Earlham College, the Cope Museum Fund, and the Test Fund. Permits for research on the Allen Cays Iguana were provided by the Bahamas Department of Agriculture to JBI.

EUTROPIS CARINATA (Common Skink), ***EUTROPIS MACULARIA*** (Rock Skink). **ENDOPARASITES.** *Eutropis carinata*, a terrestrial, diurnal skink, occurs in a wide variety of habitats in Sri Lanka, India, Bangladesh, and Nepal (Das and De Silva 2005. A Photographic Guide to Snakes and Other Reptiles of Sri Lanka. Ralph Curtis Publ., Sanibel Island, Florida. 144 pp.). *Eutropis macularia*, a semi-fossorial skink, occurs in Sri Lanka, India, Pakistan, Nepal, Bangladesh, Bhutan, east to mainland southeast Asia (Das and de Silva, *op. cit.*). There are, to our knowledge, no published records of helminths from these species. The purpose of this note is to establish the initial helminth lists for *E. carinata* and *E. macularia*.

One male *E. carinata* (SVL = 110 mm, Christopher C. Austin = CCA 2364, collected August 2002 at Buttala, Monaragala District, Central Province, Sri Lanka [6.6813°N, 81.2705°E, datum: WGS84], elev. 125 m) and one female *E. macularia* (SVL = 68 mm, CCA 1771, collected November 2002 at Batamdomba Cave, Rathapura District, Central Province, Sri Lanka [6.7797°N, 80.3969°E, WGS84], elev. 114 m) were examined for helminths. Lizards were sacrificed within 12 h of capture, preserved in 10% formalin and stored in 70% ethanol. The digestive tract was later removed, opened, and searched for helminths under a dissecting microscope. The three female nematodes found in their stomachs (1 in *E. carinata* and 2 in *E. macularia*), were removed, cleared in a drop of glycerol on a glass slide, cover-slipped, studied under a compound microscope and identified as *Physalopteroides dactylurus*. Nematodes were deposited in the United States National Parasite Collection, Bethesda, Maryland, USA as: *E. carinata* (USNPC 101175) and *E. macularia* (USNPC 101176). Lizards were deposited in the herpetology collection of the National Museum of Sri Lanka, Colombo, Sri Lanka.

Physalopteroides dactylurus is a member of the Physalopertidae, which utilizes insects as intermediate hosts (Anderson 2000. Nematode Parasites of Vertebrates. Their Development and Transmission. CABI Publishing, Oxford, UK. 650 pp.). *Eutropis* likely become infected through diet. *Eutropis carinata* and *E. macularia* are new host records for *P. dactylurus*, which is also known from *Calotes versicolor, Hemidactylus flaviviridis*, both collected in India, and *Eumeces taeniolatus* (currently *Eurylepis taeniolatus*) collected in Turkmenistan (Baker 1987. Synopsis of the Nematoda Parasitic in Amphibians and Reptiles. Memorial University of Newfoundland Occas. Pap. Biol., St. John's Newfoundland, Canada. 325 pp.)

We thank the Department of Wildlife Conservation, Sri Lanka, for scientific collecting permit (number WL/3/2/1/14/12). This research was funded in part by the People's Trust for Endangered Species and National Science Foundation grant DEB 0445213 to CCA. Sarah Goldsberry assisted with dissections.

HELODERMA SUSPECTUM (Gila Monster). **DIET AND PREDATORY BEHAVIOR.** *Heloderma suspectum* is a strict carnivore and nest-raiding specialist that shows geographic variation in its diet. Typical prey selection includes eggs of ground-nesting birds and lizards, as well as small mammals, commonly the neonates of rodents (reviewed by Beck 2005. Biology of Gila Monsters and Beaded Lizards. University of California Press, Berkeley and Los Angeles. 247 pp.; Geiger and Tracy 2008. Herpetol. Rev. 39:225–226.).

Here, we provide additional information on the diet and predatory behavior of adult *H. suspectum* from a population in the Sonoran Desert of south-central Arizona, USA. The individuals we discuss herein were subjects of a radio-telemetric study in which various features of their behavior, physiology, and spatial ecology have been investigated since March 2001 (e.g., Kwiatkowski et al. 2008. J. Zool. doi:10.1111/j.1469-7998.2008.00495.x).

The present study site, located in Pinal County, is 40 km SSE of the city of Florence, 8 km W of State Route 79, and encompasses an area of ≈ 3 km^2 at the extreme western edge of the Suizo Mountains (Iron Mine Hill). The region is ecologically designated as Arizona Upland Desertscrub subdivision (Brown 1994. Biotic Communities of the American Southwest—United States and Mexico. University of Utah Press, Salt Lake City. 342 pp.). Annual precipitation (chiefly rain) patterns are bimodal, with slight to moderate storms occurring during winter and early spring (December to March), and the strongest activity occurs from mid- to late summer (early July to mid-September), which is termed the North American monsoon (Brown 1994, *op. cit.*; Phillips and Comus 2000. A Natural History of the Sonoran Desert. The University of California Press, Berkeley and Los Angeles. 628 pp.). The area lacks permanent freestanding water, a common feature of the Sonoran Desert; at the present site, collection of rainwater in surface rocks and soil, as a rule, is transitory, and persists for only minutes to several hours. However, artificial alterations of the habitat (e.g., deep tire tracks in narrow dirt roads) occasionally provide a substantive reservoir for the collection and storage of rainwater, but even under these situations it is ephemeral, especially in summer.

On 27 April 2003, at 0923 h, in an area interfacing bajada (Phillips and Comus 2000, *op. cit.*) and desert flats, a female *H. suspectum* (HS-2: SVL = 320 mm; TL = 135 mm; body mass = 573 g) was radio-tracked and located. This individual was originally collected on 1 April 2001, and had been studied regularly since that time. She was found (Site 55, 813 m elev.) beside an active nest of Gambel's Quail; 8 clustered, normal-sized eggs were present (Fig. 1A). The nest was a shallow soil depression, located centrally in a network of Engelmann's Prickly Pear, *Opuntia engelmannii* (200 L × 100 W × 80 H cm). Nearby (3 m diam.

from nest) vegetation was sparse and limited to Triangle Bursage and Pincushion. Her core body temperature (obtained via an implanted 11.0 g temperature-sensitive radio-transmitter; Holohil Systems Ltd., Ontario, Canada) was 30.5ºC. Ambient temperature (1 m above the ground in shade) was 29.5ºC. Cloud cover was ≈ 10%, relative humidity was ≈ 15%, and wind speed was slight (0–5 kph) and intermittent.

The eight clustered eggs were inspected by HS-2 via nose-rubbing and tongue-flicking. From 0923 h to 0937 h, seven eggs were consumed at a seemingly rapid rate (0.5 eggs/min), and from 0937 h to 0947 h, the last egg was consumed. From the time the first egg was secured in her jaws, the eight eggs were consumed in 24 minutes. None of the eggs were broken prior to swallowing; each egg was slowly and gently secured in her jaws (Fig. 1A) without the aid of forelimbs. During ingestion, when the eggs were no longer visible in her mouth, cracking sounds were audible from a distance up to 3 m. When ingestion of the eggs was completed, she moved away from this site and was not re-located for 7 days. The previous day (26 April 2003), at 1800 h, HS-2 was located at Site 2 (elev. 826 m), a large triangular rock slab, which was located in the western-most area of the Suizo Mountain complex (Iron Mine Hill); she demonstrated fidelity to Site 2 on multiple occasions since using it first on 13 April 2001. The minimum distance traveled between the two sites (2 and 55) was 215 m and accomplished in < 15 h.

On 11 May 2004, at 1831 h, in bajada, a male *H. suspectum* (HS-7: SVL = 334 mm; TL = 151 mm; body mass = 673 g) was radio-tracked and located (Site 19, elev. 821 m). This individual

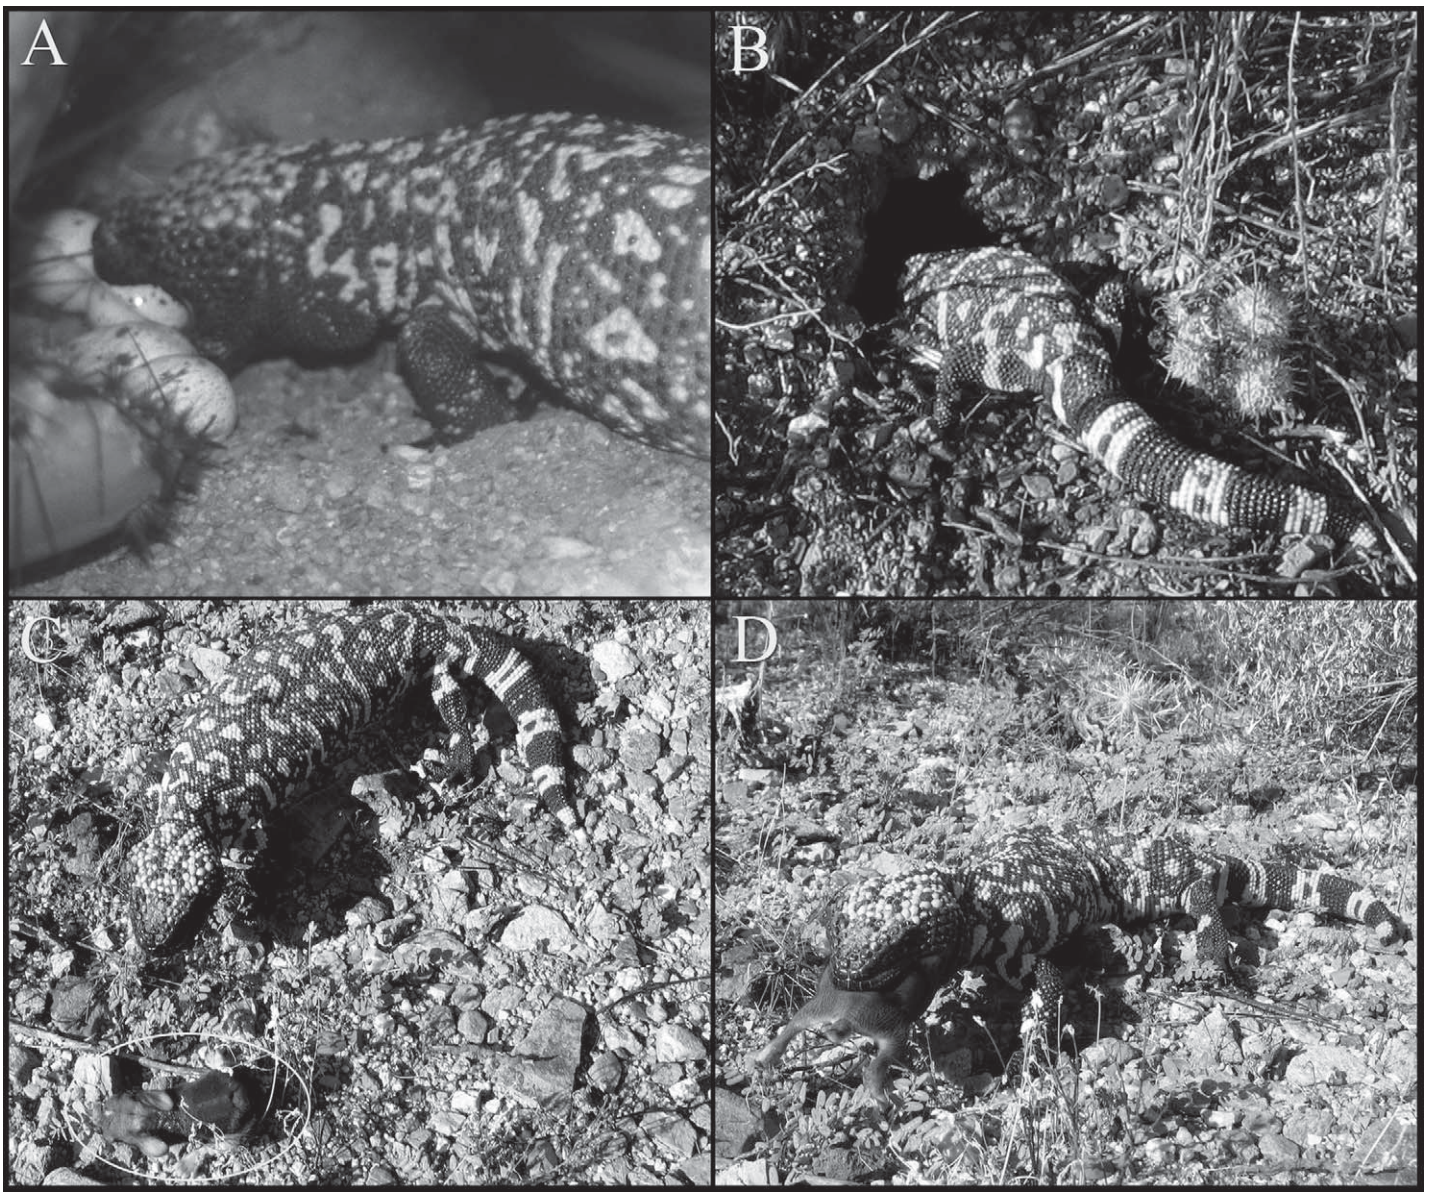

FIG. 1. Predation by adult wild-living Gila Monsters, *Heloderma suspectum*. A) An adult female (HS-2) at the nest of a Gambel's Quail in the process of securing an egg to ingest. Eight eggs were observed at the nest and all were ingested. B–D) An adult female (HS-13) in various stages of consuming neonates of Desert Cottontails (*Sylvilagus audubonii*). B) Female HS-13 was first located entering a burrow. C) Female HS-13 is next to the first neonatal rabbit (within the yellow ellipse). Note the extensive torn skin in the area of the neck. D) The neonate in Fig. 1C is being consumed head-first. All photographs by R. A. Repp.

was originally collected on 23 February 2003, and had been studied regularly since that time. He was found 30 cm W of an active Gambel's Quail nest; 6 clustered, normal-sized eggs were present. He appeared to be moving away from the nest at our approach, likely as a result of our sudden presence. The nest was located on the west side of a stand of Engelmann's Prickly Pear, which was circular-shaped (110 H cm × 200 cm in diam.). Nearby (3 m diam. from the nest) vegetation was Triangle Bursage, Buckhorn Cholla (*Opuntia acanthocarpa*), and Pincushion. His core body temperature (obtained via a 11.0 g temperature-sensitive radio-transmitter; Holohil Systems Ltd) was 31.3ºC. Ambient temperature was 30ºC, and ground temperature in the sun ("hot spot") was 34.0ºC. Cloud cover was 0%, relative humidity was ≈ 10%, and wind speed was slight to moderate (5–20 kph) and intermittent. Because our presence seemed to distress HS-7, we promptly left this site.

At 1947 h, we radio-tracked HS-7 a second time; he was re-located at a previously used location (Site 18, elev. 826 m) on the western edge of Iron Mine Hill, which was 37 m NW of Site 19. His core body temperature was 28.8ºC. Ambient temperature was 25ºC. Wind speed was slight (0-5 kph) and intermittent. At 1956 h, we returned to Site 19 and inspection revealed that all 6 eggs were gone; we thus presumed they had been consumed by HS-7. Similar to our observations of HS-2, we found no signs that the eggs had been broken during feeding (e.g., no yolk or shell fragments).

On 9 August 2008, at 0820 h, in bajada, a female *H. suspectum* (HS-13: SVL = 310 mm; TL = 146 mm; body mass = 466 g) was radio-tracked and located (Site 9, elev. 825 m). This individual was originally collected on 24 May 2008, and had been studied regularly since that time. She was found with her head and midbody in a north-facing burrow (Fig. 1B) that was 75 mm diameter. The burrow was situated between two clumps of Triangle Bursage (each ≈ 400 m height). Nearby plants included Pincushion. Her core body temperature (obtained via an implanted 11.0 g temperature-sensitive radio-transmitter; Holohil Systems Ltd) was 35.5ºC. Ambient temperature was 29.5ºC and the hot spot was 41.0ºC. Cloud cover was ≈ 10 %, relative humidity was ≈ 30%, and wind speed was slight (0–5 kph) and intermittent.

Muffled vocalizations (repetitious cat-like mews, 1 sec apart, presumed from a single individual) were heard emanating from the burrow; these calls were distinctive and could be heard several meters from the site. At 0821 h, her tail was grabbed, and she was quickly removed from the burrow and placed on the ground ≈ 1 m from the burrow. During this transfer, a neonatal Desert Cottontail (*Sylvilagus audubonii*), estimated to be 40–50 g, was gripped in her jaws but was dropped as she was placed on the ground. For about 1 min, the neonate was writhing and rapidly vocalizing while HS-13 re-located and inspected it; the neonate had severe lacerations with oozing fluids (Fig. 1C). At 0822 h, HS-13 began ingesting the neonate headfirst (Fig. 1D), which was completed in 3 min. At 0825 h, HS-13 returned to and stayed at the nest; she entered to midbody. Muffled vocalizations from a single neonate were heard; at 0830 h, the vocalizations stopped. Apparently, the neonate producing the vocalizations had been consumed. At 0831 h, with no further signs of predatory activity, HS-13 was gently removed from the burrow a second time, and it was noted that she had rabbit fur clinging to her jaws. The nest was gently and non-invasively inspected at 0832 h. It was shallow (120 mm), the cavity was larger than the entrance, and the substrate was lined with fur (presumably of the mother) and grasses (Bowers et al. 2004. Mammals of North America. Houghton Mifflin Co., New York. 352 pp.). During this assessment, no further neonates were detected. HS-13 re-entered the nest at 0833 h, inspected it for several minutes, then exited at 0837 h, traveling N of the burrow; she was not re-located until a later date (16 August 2008).

We cannot determine whether HS-13 bit and envenomated the first neonate prior to our grabbing and removing her from the burrow/nest (see Beck 2005, *op. cit.*). Clearly, she was startled by this procedure, and there is little doubt that the neonate was damaged (and possibly envenomated) by this intrusion. Nonetheless, based on the presence of vocalizations prior to our disturbances, it is possible that biting and envenomation occurred prior to our arrival. Similarly, the second neonate we heard vocalizing from the burrow/nest might have been bitten and envenomated. Furthermore, although we show that HS-13 consumed at least two neonates, it is possible that there were others eaten because litter size in *S. audubonii* is typically greater than two (Beck 2005, *op. cit.*).

Support for our field studies at the Suizo Mountains are from Arizona State University, Zoo Atlanta, Georgia State University, and David L. Hardy, Sr. Since 2001, many individuals provided assistance in radio-tracking, but most noteworthy are Hans-Werner Herrmann and Ryan Sawby. Also, Ryan Sawby provided invaluable assistance with photography and identification of plants and invertebrates. This study was approved by the animal care committee (IACUC) of Arizona State University (98-429R), and appropriate scientific permits were obtained from the Arizona Game and Fish Department.

Submitted by **ROGER A. REPP**, National Optical Astronomy Observatory, 950 North Cherry Avenue, Tucson, Arizona 85719, USA (e-mail: repp@noao.edu); and **GORDON W. SCHUETT**, Department of Biology and Center for Behavioral Neuroscience, Georgia State University, 33 Gilmer Street, Unit 8, Atlanta, Georgia 30303-3088, USA (e-mail: biogws@langate.gsu.edu, or gwschuett@yahoo.com).

HEMIDACTYLUS FRENATUS (Common House Gecko). **BROOD**. On 9 February 2008, two gravid female *Hemidactylus frenatus* (SVL = 49.19 mm, tail length = 40.62 mm, mass = 2.365 g; SVL = 44.06 mm, tail length = 52.12 mm, mass = 2.360 g) were obtained from Poza Larga, Municipio Espinal Veracruz, Mexico (20.1608333°N, 97.5094444°W), and brought to the laboratory. Specimens were maintained in separate plastic boxes measuring 32 × 21 × 15 cm with newspaper as substrate, fresh water, and an ambient temperature of 28.5ºC.

On the morning of 10 February 2009, each female produced a clutch of two eggs, which were placed in an incubator at 28–30ºC with 50–70% humidity in plastic boxes with agrolite substrate. The first hatchling emerged on 17 March (37 days post oviposition [dpo]) and measured 19.6 mm SVL, 18.8 mm tail length, 0.19 g. The second hatchling emerged on 19 March (39 dpo) and measured 13.1 mm SVL, 14.1 mm tail length, 0.16 g. The third hatchling emerged on 25 March (45 dpo), and measured 16.1 mm SVL, 20.9 mm tail length, 0.21 g. The fourth hatchling emerged on 2

April (53 dpo), and measured 18.7 mm SVL, 19.6 mm tail length, 0.21g. Mean incubation period lasted 43.5 days, shorter than those presented in Krysko et al. (2003. Amphibia-Reptilia 24:390–396), who reported incubation times of 48–55 days at 28–29ºC.

Submitted by **BEATRIZ RUBIO MORALES**, **EDUARDO CID MENDEZ,** and **FELIPE CORREA SÁNCHEZ** (e-mail: corsanfel@gmail.com), Laboratorio de Herpetología, FES Iztacala UNAM, Avenida de los Barrios 1, P.O. Box 54090 Tlalnepantla, Estado de México, México.

IGUANA IGUANA (Green Iguana). **AGGRESSIVE BEHAVIOR**. Male green iguanas are reported to defend small territories in which variable numbers of females and sub-adults males reside (Muller 1972. Zool. Beitr. 18:109–131). Dominant males use varied displays to defend their territory. These displays involve vertical head and body movements (head bob) as well as tail slapping, often accompanied by dewlap extensions (Dugan 1982. Anim. Behav. 30:327–338). Reports in literature on display behavior of *I. iguana* are common, but descriptions of males engaging in contact fights are rare. We report here on aggressive behavior in which two males were observed fighting violently and biting each other.

At 1300 h on 28 May 2008, we observed two male *I. iguana* of approximately the same size (120 cm from snout to tip of tail) fighting on a ranch near the Abobral River in the Pantanal of Mato Grosso do Sul, Brazil (56.9177111°W, 19.4762333°S, datum: WGS84, elev. 60 m). Both males were on the ground in an open grassland ca. 10 m away from trees bordering a marsh. The males were seen lunging, biting each other and thrashing on the ground (Figs. 1A–B). They interlocked for less than five minutes, until finally one male escaped. The remaining male displayed, using vertical head movements while extending the dewlap for ca. 5 min before retreating to the forested area near the marsh (Fig. 1C). Both males sustained superficial wounds on their flanks and one male's front right leg was injured.

Iguana iguana has an annual reproductive cycle and maximum testicular development in the Pantanal occurs between June and September with a peak in June (Ferreira et al. 2002. Brazil. J. Morphol. Sci. 19:23–28). Oviposition occurs between September and December (Campos 2004. Herpetol. Rev. 35:169). Hence, this behavior may be related territorial defense for access reproductive females.

Submitted by **ARNAUD L. J. DESBIEZ,** Royal Zoological Society of Scotland Edinburgh, EH12 6TS, United Kingdom (e-mail: adesbiez@hotmail.com or adesbiez@cpap.embrapa.br); and **ZILCA CAMPOS**, Embrapa Pantanal CP 109 Corumbá MS 79320-900 Brazil (e-mail: zilca@cpap.embrapa.br).

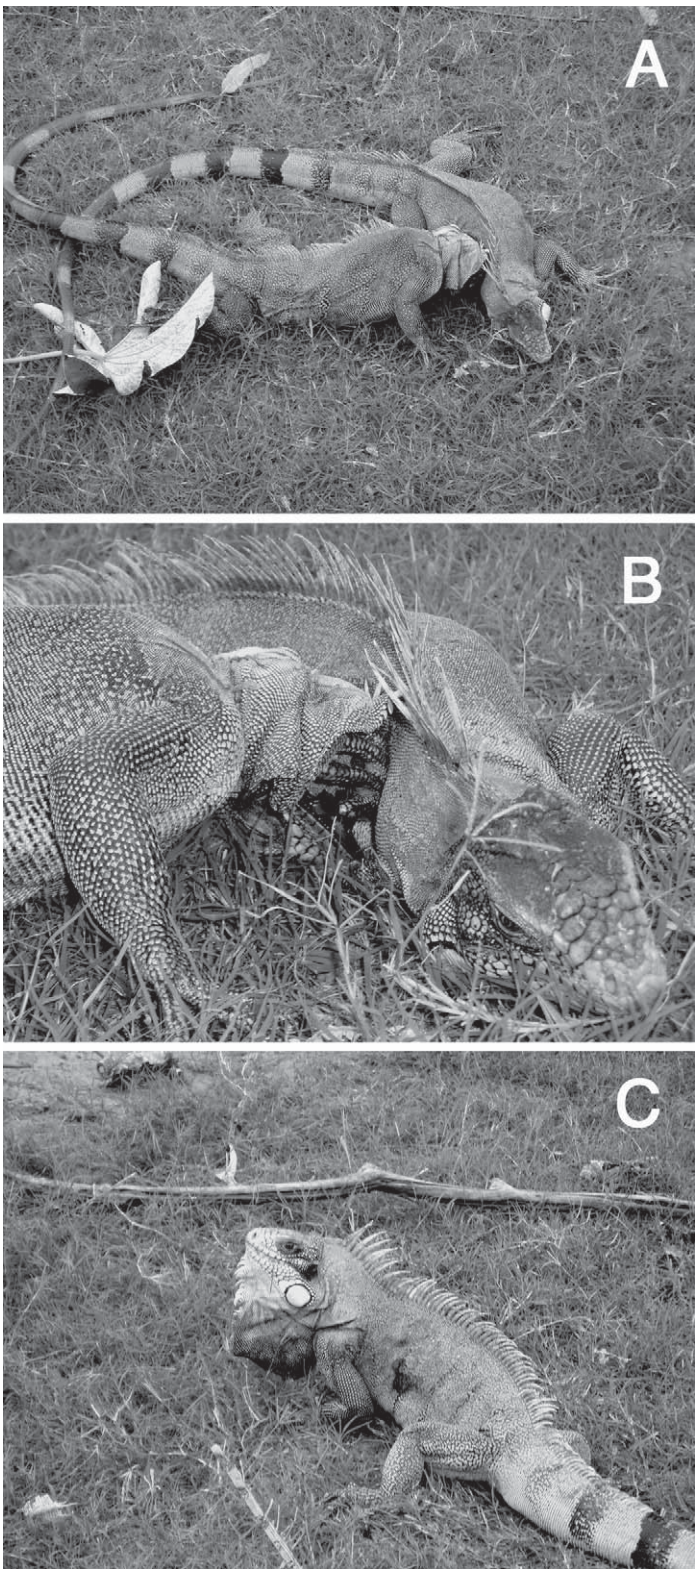

FIG. 1. A–B. Male *Iguana iguana* engaging in interlocking biting behaviors in the Brazilian Pantanal, May 2008. C) Victorious male iguana displaying after the fight. Note the superficial wound on the animal's flank.

LYGOSOMA PUNCTATA (Spotted Supple Skink). **ENDOPARASITES.** *Lygosoma punctata* is a diurnal, fossorial skink that is widepread in Sri Lanka, India, Bangladesh, and Pakistan (Das and de Silva 2005. A Photographic Guide to Snakes and Other Reptiles of Sri Lanka. Ralph Curtis Publ., Sanibel Island, Forida. 144 pp.). To our knowledge, the only helminth recorded from *L. punctata* is the nematode, *Thelandros* sp. (Lakshimi et al. 1985. Ind. J. Helminthol. 2:115–125). The purpose of this note is to add the nematode *Parapharyngodon adamsoni* to the helminth list of *L. punctata*.

Two female *L. punctata* (SVL = 60 mm, Christopher C. Austin = CCA 2367 collected at Tampataya, Ampara District, Eastern Province [7.5996°N, 81.4272°E, WGS 84], elev, 20 m; and SVL = 49 mm, CCA = 2400 collected 2 km N central Puttalam, Puttalam District, North Western Province, Sri Lanka [8.0742°N, 79.7956°E, WGS 84], elev. 0 m) were examined for helminths. Lizards were sacrificed within 12 h of capture, preserved in 10% formalin, and stored in 70% ethanol. The digestive tract was removed, opened, and searched for helminths. The five nematodes found (CCA 2367 1 m, 2 f; CCA 2400 2 f) in their stomachs were removed, cleared in a drop of glycerol on a glass slide, cover-slipped, studied under a compound microscope, and identified as *Parapharyngodon adamsoni*. Nematodes were deposited in the United States National Parasite Collection, Bethesda, Maryland as (USNPC 101177). Lizards were deposited in the herpetology collection of the National Museum of Sri Lanka, Colombo, Sri Lanka.

Parapharyngodon adamsoni was described from *Chalcidoceps thwaitesi*, *Nessia smithi* (currently *Nessia bipes*), and *N. burtoni* by Crusz and Daundasekera (1988. Ann. Parasitol. Hum. Comp. 63:439–447.). *Parapharyngodon adamsoni* is in the family Oxyuridae which has a direct life cycle with no intermediate host (Anderson 2000. Nematode Parasites of Vertebrates. Their Development and Transmission. CABI Publishing, Oxford, UK. 650 pp.). Infection likely occurs through ingestion of eggs. *Lygosoma punctata* represents a new host record for *P. adamsoni*.

We thank the Department of Wildlife Conservation, Sri Lanka for permission (number WL/3/2/14/12). This research was funded in part by the People's Trust for Endangered Species and National Science Foundation grant DEB 0445213 to CCA. Sarah Goldsberry assisted with dissections.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); **CHARLES R. BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb@ppsu.edu); **INDRANEIL DAS**, Institute of Biodiversity and Environmental Conservation, Universiti Malaysia Sarawak, 94300, Kota Samarahan, Sarawak, Malaysia (e-mail: idas@ibec.unimas.my); **ANSELM DE SILVA,** Amphibian and Reptile Research Organization of Sri Lanka, 15/1 Dolosbage Road, Gampola, Sri Lanka (e-mail: kalds@sitnet.lk); and **CHRISTOPHER C. AUSTIN,** Department of Biological Sciences and Museum of Natural Science, Louisiana State University, Baton Rouge, Louisiana 70803, USA (e-mail: ccaustin@lsu.edu).

MESOSCINCUS MANAGUAE (Managua Skink). **ENDOPARASITES.** *Mesoscincus managuae* is known from southern Honduras to Costa Rica (Köhler 1999. The Amphibians and Reptiles of Nicaragua. A Distributional Checklist with Keys. Cour. Forsch.-Inst. Senckenburg, Frankfurt a. M. 213:1–121). To our knowledge, there are no reports of helminths from *M. managuae*. The purpose of this note is to establish an initial helminth list for *M. managuae*.

One female *M. managuae* from the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California collected in December 1964 in Nicaragua, Granada Department, near Isletas (11.7500°N, 85.3333°W, WGS84; elev. 10 m) was examined for endoparasites (LACM 37975; SVL = 85 mm). The body cavity was opened and the digestive tract examined under a dissecting microscope. Found in the large intestine were one fourth stage female and one male nematode which were cleared in a drop of glycerol on a glass slide, cover-slipped, and identified using a compound microscope as *Parapharyngodon alvarengai*. Nematodes were deposited in the United States National Parasite Collection, Beltsville, Maryland as *Parapharyngodon alvarengai* (USNPC 101743).

Parapharyngodon alvarengai was originally described from *Mabuya maculata* from Brazil (Freitas 1957. Mem. Institut. Oswaldo Cruz 55:21–45) and later reported in *Ameiva ameiva* (Vicente et al. 1993. Rev. Brasil. Zool. 10:19–168) and *Rhinella icterica* (Luque et al. 2005. Acta Parasitol. 50:215–220), both hosts from Brazil. It was also reported from the lizards *Anolis nebulosus*, *Phyllodactylus lanei*, and *Sceloporus nelsoni* collected in Mexico (Moravec et al. 1997. J. Helminthol. Soc. Washington 64:240–247; Mayén-Peña and Salgado Maldonado 1998. J. Helminthol. Soc. Washington 65:108–111). *Parapharyngdon alvarengai* is a member of the Oxyuridae, which do not utilize intermediate hosts (Anderson 2000. Nematode Parasites of Vertebrates: Their Development and Transmission, 2nd ed. CABI Publishing, Oxfordshire, UK. 650 pp.). Infection of *M. managuae* presumably occurred via exposure to *P. alvarengai* eggs in fecally contaminated substrate. *Mesoscincus managuae* represents a new host record for *P. alvarengai*. Nicaragua is a new locality record.

We thank Christine Thacker (LACM) for permission to examine *M. managuae* and Cecilia Nava (Whittier College) for assistance with dissections.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); and **CHARLES R. PHRYNOSOMA ASIO (Giant Horned Lizard). **DIET**. *Phrynosoma asio* is the largest member of the genus, occurring along the Pacific Coastal forests of Colima, Mexico south to northern Guatemala (Baur and Montanucci 1998. Krötenechsen. Herpeton, Offenbach. 158 pp.; Sherbrooke 2003. Introduction to Horned Lizards. Univ. California Press, Berkeley. 178 pp.). Little is known of the natural history of *P. asio*, but previous reports on the diet of this species show that it is more of a generalist and less myrmecophagous than congeners (Lemos-Espinal et al. 2004.

Herpetol. Rev. 35:131–134; Montanucci 1989. Herpetologica 45:208–216; Pianka and Parker 1975. Copeia 1975:141–162).

On 3 August 2008, Ian M. Recchio, Chris M. Rodriguez, Brett Baldwin, and Carlos Martinez collected 4 male and 2 female sub-adult (mean SVL = 50.0 mm) *P. asio* in tropical deciduous forest in Municipio de Ixtlahuacan, Colima, Mexico (19.03°N, 103.779°W). All six individuals were observed in late afternoon between 1400 and 1700 h, associated with secondary growth clearings adjacent to primary tropical deciduous forest, resting near or underneath bunchgrass. Fecal samples were obtained while the lizards were held prior to export. While being transported for export, the feces from the lizards were preserved for content analysis. Fecal samples were preserved in 75% isopropyl alcohol and examined for contents. The grouped fecal samples contained the remains of the following insect taxa: 56 *Aphaenogaster ensifera* (Formicidae, Myrmicinae), 23 larvae of an undetermined species of tortoise beetle (Chrysomelidae, Cassidinae), over 400 termites (Isoptera), three toad bugs (Gelastocoridae, *Nerthra fuscipes*), a single dung beetle (Scarabaeidae, Scarabaeinae, *Canthon* sp.), and several pieces of unidentifiable insect material. Our sample shows *P. asio* feeds on a variety of terrestrial insects including, but not limited to, ants and termites. This is consistent with previous studies.

All research and collecting were done under the authority of SEMARNAT scientific research permit SGPA/DGVS/03804 issued to IR.

PHRYNOSOMA CORNUTUM (Texas Horned Lizard). **REPRODUCTION.** We observed copulation between *Phrynosoma cornutum* on multiple occasions. On 3 May 2008 at 1250 h in Oklahoma Co., Oklahoma, USA, while conducting radiotelemetry observations on a male (61.0 mm SVL) *P. cornutum*, one of us (MTC) observed copulation with a radio-transmittered female (62.9 mm SVL) (Fig. 1). Both individuals were fitted with Holohil model BD-2 transmitters (0.9 g, male; 1.5 g, female), with transmitters attached to the dorsal surface using silicone sealant and secured around the neck by an elastic collar. The same male was observed copulating with another female (70.0 mm SVL) on 16 May 2008 at 0715 h and with a third female (69.5 mm SVL) on 20 May 2008. The latter two females were not fitted with transmitters.

These observations are significant in that they confirm that our technique of transmitter attachment does not prevent coitus in our study animals, and also provides direct evidence for the polygynous mating strategy of male *P. cornutum*.

PODARCIS BOCAGEI (Bocage's Wall Lizard). **SPINAL FRACTURE**. Pathologic spinal fractures can occur in reptiles as the result of metabolic bone disease (Bennett and Mehler 2006. *In* Mader [ed.], Reptile Medicine and Surgery, 2nd ed., pp. 244–245. Saunders Elsevier, St. Louis, Missouri), but in some cases they have also been reported to result from spinal osteopathies (Bennett and Mehler, *op. cit.*; Fitzgerald and Vera 2006. *In* Mader [ed.], *op. cit.*, pp. 909–910 and periosteal newbone formation due to undetermined causes (Fitzgerald and Vera, *op. cit.*). Reptiles with spinal cord fractures may present paralysis (Mader 2006. *In* Mader [ed.], *op. cit.*, p. 847) and reptiles with spinal cord injury generally have a loss of panniculus response caudally to the site of injury and a loss of tail or vent stimulation reflex (Bennett and Mehler, *op. cit.*). In some cases, hypertonia occurs cranial to the site of the injury (Bennett and Mehler, *op. cit.*). A reptile with paralysis and spinal fracture can loose its ability to urinate and defecate (Mader, *op. cit.*). Here, we report on a case of spinal fracture in a wild lacertid lizard from Portugal.

During the radiographical examination of specimens of *Podarcis* undergoing experiments on locomotor performance, we detected an adult female *P. bocagei* (55.9 mm SVL) with a conspicuous spinal fracture. The lesion affected the thoracic vertebrae, next to the front limbs (Fig. 1) and we observed evidence of reossification of the vertebrae cranially and caudally the fracture.

This female had been collected 26 days earlier in São Mamede do Coronado, near Trofa, northwestern Portugal (41.2853°N, 8.5745°W; datum: WGS 1984 ; elev. 50 m), in a habitat consisting of agricultural fields separated by granite formations where lizards found refuge and attained high densities. The female displayed no obvious locomotor deficiencies before or after the radiographies. In fact, before being submitted to the x-ray revealing the malformation, this individual had participated in several

experiments consisting of different locomotion trials. Nonetheless, during preliminary analysis of the data (video footage), a slight difference in this individual's running pattern was noted, consisting of a "wriggling" or undulating movement different from all other specimens (N = 26) included in the study. Currently, detailed quantification of the locomotion parameters is being carried out, which may provide more information on the exact impact of the injury on the locomotor capacities of the lizard. While the lizard was kept in the laboratory (for total period of 27 days), we detected no differences in drinking, feeding, defecating, or urinating habits between this individual and remaining lizards. Radiographs of the 26 other specimens (14 males, 12 females) from the same population revealed no fractures or anomalies of any kind. X-rays from a previous study that included 162 *P. bocagei* and 168 *P. carbonelli* (Kaliontzopoulou et al. 2008. Amphibia-Reptilia 29:288–292) also revealed no individuals with fractures or malformations.

Though other kinds of vertebral malformations have frequently been observed in lizards, mostly are related to the metabolic bone disease suffered by many captive bred reptiles and usually result in either scoliosis/lordosis or bone demineralization (Grogan 1976. J. Herpetol. 10:262–263; Ahboucha and Gamrani 2001. Metabolic Brain Dis. 16:219–226; Mitchell and Georgel 2005. Herpetol. Rev. 36:183–184). The fracture we observed could be a case of spinal osteopathy or trauma, but we can not assess these hypotheses through radiography (all the individuals used were released to their place of capture after the experiment was completed). However, independent of its exact cause, this represents an exceptional case of recovery from a fracture that typically would have become lethal, either directly by causing a fracture in the spinal cord or indirectly by causing paralysis and consequently making the lizard unable to carry on its normal activities. The low frequency with which such a fracture was observed (only one out of more than 300 individuals of two closely related species of the genus) might indicate that such fractures typically are lethal and rarely seen in free-ranging animals.

Special thanks to H. Fernandes from Park & Zoo Santo Inácio who provided X-rays, and W. Grogan for providing references related to vertebral anomalies in reptiles.

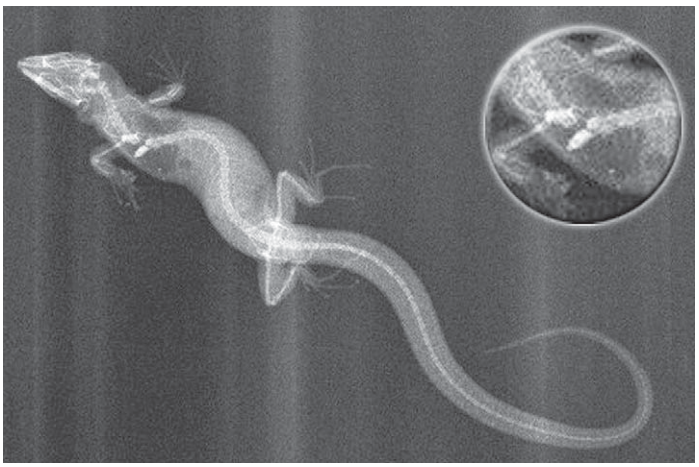

FIG. 1. X-ray of an injured female *Podarcis bocagei*. Detail of the fractured vertebral area can be seen in the round inset at upper right. The 36 Kv X-ray was taken with an exposure of 3mA/sec for 0.03 sec.

PRISTIDACTYLUS SCAPULATUS (NCN). **SAUROPHAGY**. *Pristidactylus* are generally considered to be insectivorous (Cei1993. Reptiles del Noroeste, Nordeste y Este de la Argentina. Mus. Reg. Sci. Nat. Torino Monogr. 14:1–949), but specific diet data are lacking for most species. Hence, here we report an observation of saurophagy in *P. scapulatus*.

At 1213 h on 13 December 2007, we observed an adult male *P. scapulatus* (100 mm SVL; 26 mm mouth width) attack and start to eat an adult (51 mm SVL) male *Liolaemus ruibali* at the Reserva Uso Multiple Don Carmelo, Sierra de la Invernada, Departamento Ullum, San Juan, Argentina (30.5862°S, 69.0964°W; datum: WGS84; elev. 3100 m). The habitat where the observation was dominated for shrubs of *Adesmia subterranea*, *Adesmia horrida* and *Licyum chañar*, this is vegetation typical to the Puna (M. Almirón, pers. comm.). When captured, the *P. scapulatus* released the *L. ruibali*, which was unable to move and died soon thereafter. To our knowledge, this is the first record of attempted saurophagy for any species of *Pristidactlyus*.

We thank M. Jordán for permission to conduct research at the Reserva Don Carmelo (permit Nº 1204-2235-070), R. Espinoza and F. Lobo for assistance in the field, and M. Almirón for identification of the vegetation.

SCELOPORUS MAGISTER (Desert Spiny Lizard). **PREY.** Members of the *Sceloporus magister* species group (Schulte et al. 2006. Mol. Phylogen. Evol. 39:873–880) are often reported to be generalized feeders (Parker and Pianka 1973. Herpetologica 29:143–152; Vitt and Ohmart 1974. Herpetologica 30:410–417). However, studies show that invertebrates are far more representative in the diet than vertebrates. Documented prey items include insects (especially Hymenoptera [mostly ants], Coleoptera, Hemiptera, and various larvae), spiders, and other invertebrates (Hotton 1955. Am. Midl. Nat. 53:88–114; Johnson 1966. Am. Midl. Nat. 76:504–509; Parker and Pianka 1973, *op. cit.*; Tanner and Krogh 1973. Great Basin Nat. 33:133–146; Vitt and Ohmart 1974, *op. cit.*). Vegetation is also reported in the diet in these studies, but it

is not clear how much plant material is secondarily ingested along with invertebrate prey.

Vertebrate prey, especially lizards, is widely reported in general literature, but is based on relatively few records in the primary literature (Cardwell 1994. Herpetol. Rev. 25:121–122). Parker and Pianka (1973, *op. cit.*) reported a single unidentified vertebrate in their sample of the stomach contents of 123 specimens in the *S. magister* complex (*S. magister* + *S. bimaculosus* + *S. uniformis*, *fide* Schulte et al. 2006, *op. cit.*) and Vitt and Ohmart (1974, *op. cit.*) reported a single *Aspidoscelis tigris* from the sample of stomach contents of 66 specimens (*S. magister* + *S. uniformis*, *fide* Schulte et al. 2006, *op. cit.*). Perkins et al. (1997. Herpetol. Rev. 28:89) reported *Xantusia vigilis* in the diet of these lizards in the Mojave Desert (hence, *S. uniformis*, *fide* Schulte et al. 2006, *op. cit.*). Intraspecific predation upon neonates has also been reported (Tanner and Krogh 1973, *op. cit.*; Cardwell 1994, *op. cit.*). Jones and Schwalbe (2009. *In* Jones and Lovich [eds.], Lizards of the American Southwest: A Photographic Field Guide, pp. 226–229. Rio Nuevo Publishers, Tucson, Arizona) report "nestlings" in the diet of *S. magister*, but the details are not reported. However, we are aware that the source of this report comes from a reliable personal observation by R. Smith, Tucson, Arizona, of an adult *S. m. magister* feeding on a nestling Gambel's Quail (*Callipepla gambelii*) in a Tucson suburb.

To our knowledge, there are no records of *S. magister* (or any species of the complex) attempting to feed on mammalian prey. At 0900 h on 13 October 2008, one of us (WBG) heard squeals that were coming from the direction of an outside wall of a house in Tucson, Pima Co., Arizona. An adult *S. m. magister* had the left wing of a Western Pipistrelle Bat (*Pipistrellus hesperus*) in its mouth. The lizard and the bat were under a wooden false shutter next to a window on a south-facing wall (Fig. 1). The bat struggled for ca. 15 min before freeing itself and dropping to the ground. The bat remained on the ground for at least 15 more minutes, the duration of the observation. The lizard stayed in place and did not attempt to interact with the bat again during that time. The next morning the bat was gone, but the lizard was not. It seems likely this event was an attempt at predation, but other behavioral traits (e.g., territorial aggression) cannot be completely ruled out.

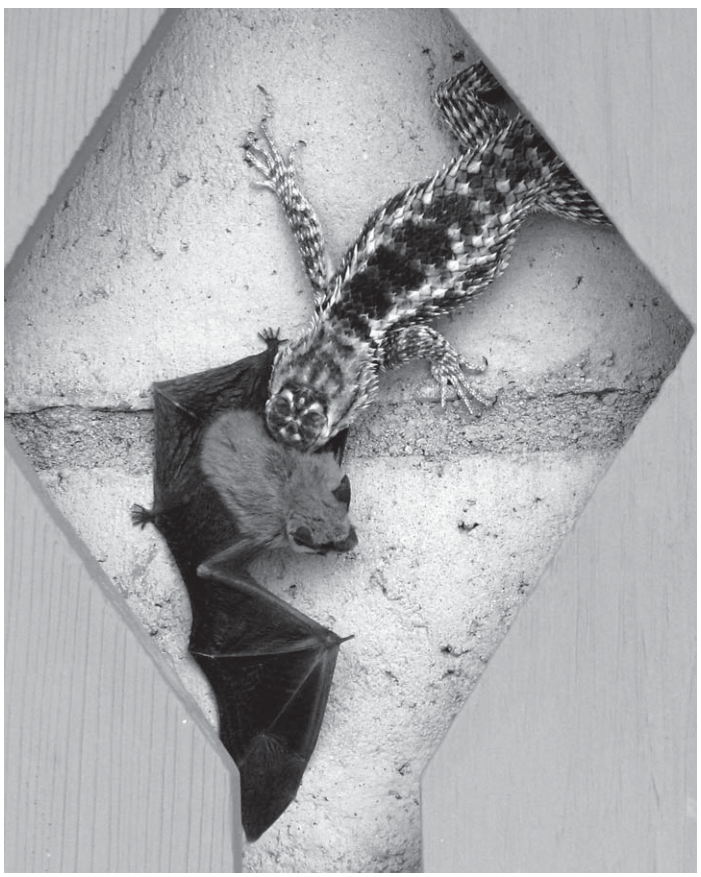

FIG. 1. Adult *Sceloporus m. magister* apparently attempting to prey on a bat, *Pipistrellus hesperus*. Photograph by W. B. Gillespie.

The identity of the lizard was verified by Cecil Schwalbe (U.S. Geological Survey, Tucson, Arizona) and the bat's identity was verified by Tim Snow and Angie McIntire (Arizona Game and Fish Department) and Ronnie Sidner (University of Arizona).

TROPIDURUS HISPIDUS (NCN). **MINIMUM SIZE AT MATURITY; MAXIMUM BODY SIZE**. *Tropidurus hispidus* has a broad distribution from central-eastern and northeastern Brazil to Venezuela (Rodrigues 1987. Arq. Zool. 31:105–230). The minimum size at sexual maturity is ≥ 70 and ≥ 71 mm, for females and males, respectively based on a series from northeastern Brazil (Vitt 1995. Occ. Pap. Oklahoma Mus. Nat. Hist. 1:1–29). Vitt (1995, *op. cit.*) also reported the maximum body size for adult female and male *T. hispidus*, respectively, as 107 and 129 mm. Herein, we report a new record for minimum size at maturity and for maximum body size for both sexes of this species in a caatinga at the Estação Ecológica do Seridó (ESEC Seridó), Serra Negra do Norte municipality, Estado do Rio Grande do Norte, Brazil.

To study the reproductive ecology of *Tropidurus* in rocky habitats at ESEC Seridó (06.57672°S, 37.25575°W, datum: WGS84; elev. 192 m), we collected a large series of *T. hispidus* (nine juveniles, 75 adults). Of the 75 adult lizards (25 males, 50 females), three females (collected on 6 February 2007 and 23–24 January 2008, respectively) with SVLs of 67.8, 65.5, and 65.0 mm had vitellogenic follicles. Also, one male (SVL = 68 mm) collected on 7 February 2007 had testes and epididymides containing mature spermatozoa in the lumen, and showed secondary sexual characteristics (a black stripe on the ventral aspect of each thigh and a black compact spot in the pre-cloacal flap.; Vanzolini et al. 1980. Répteis das Caatingas. Acad. Bras. de Ciênc., Rio de Janeiro, Brazil. 161 pp.). Thus, for the purpose of our study, we regarded the SVL of the smallest reproductive female as the minimum size for sexual maturity and all females ≥ 65 mm were considered adults. Also, all males with SVL ≥ 68 mm were regarded as adults. These sizes at sexual maturity precede the previous minima for females by 5 mm and for males by 3 mm. With relation to the maximum body size, we recorded a 113 mm SVL adult female on 21 November 2007, and a 139 mm SVL adult male on 13 December 2007. These sizes exceed the previous maxima for females by 6 mm and for males by 10 mm.

Specimens of *T. hispidus* (CHBEZ 1589, 1592, 1961, 1974, 1983, 1987) were deposited in the herpetological collection of Universidade Federal do Rio Grande do Norte, Natal City. We thank the Programa PELD/CNPq – Caatinga: Estrutura e Funcionamento for logistic support, and R. Hansen for helpful comments on this note. This study was supported by a grant from the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) to L. Ribeiro (Process 141993/2006-5), and IBAMA provided a permit (Permit 206/2006 and Process 02001.004294/03-15).

Submitted by **LEONARDO B. RIBEIRO** (e-mail: ribeiro.lb@gmail.com), and **ELIZA M. X. FREIRE** (e-mail: elizajuju@ufrnet.br), Programa de Pós-Graduação em Psicobiologia, Universidade Federal do Rio Grande do Norte, Centro de Biociências, Caixa Postal 1511, Campus Universitário Lagoa Nova, CEP 59078-970, Natal, Rio Grande do Norte, Brazil.

TROPIDURUS MONTANUS (Calango-da-Montanha; Montane Collared Lizard). **ESCAPE BEHAVIOR**. Some knowledge of behavior is crucial for understanding an animal's ecology, yet for many vertebrates, we lack even anecdotal information is lacking (Greene 1986. *In* Feder and Lauder [eds.], Predator-Prey Relationships, pp. 99–108. University of Chicago Press, Chicago, Illinois; Greene 2005. Trend. Ecol. Evol. 20:23–27). Lizards are known to present diverse defensive behaviors to avoid predation, including crypsis, immobility, mimicry, chemical defense, tail or skin shedding, social and aggressive displays, and use of retreats or escape routes (Pianka and Vitt 2003. Lizards: Windows to the Evolution of Diversity. University of California Press, Berkeley. 348 pp.). *Tropidurus montanus* is a small, diurnal, terrestrial lizard, endemic to the open, montane habitats of southern Espinhaço range (Rodrigues 1987. Arq. Zool., São Paulo 31:105–230). The defensive behavior of *T. montanus* was recently studied (Machado et al. 2004. S. Am. J. Herpetol. 2:136–140) and the primary strategy of defense is the predator avoidance through crypsis associated with immobility. When disturbed, locomotor escape was the tactic employed by this species (Machado et al., *op. cit.*). Here, we describe an unreported defensive behavior in *T. montanus*, and a novelty among *Tropidurus* lizards.

At 1210 h on 16 March 2008, we observed an adult male *T. montanus* (80.6 mm SVL, 117.4 mm tail length) dive into a small stream after being chased by one of us. The observation occurred in Serra do Cabral, Augusto de Lima municipality, Espinhaço range, Minas Gerais State, Brazil (17.999500°S, 44.337028°W; datum: WGS84; elev. 1016 m). After having been disturbed, the lizard fled on the rocks and dove to a depth of ca. 10 cm into a small stream and remained underwater over 3.5 min. Throughout this time, the animal kept its head partly oriented toward the surface and its eyes partially opened, presumably observing the surface and our movements. Three minutes after the observation began, the animal was visibly experiencing difficulties remaining under water, and bubbles escaped through its nostrils. Just over 3.5 min after the observation began, it tried to escape sideways on the rock where it was submerged, and was captured.

Diving behavior would allow *T. montanus* opportunity to escape a predator during a risky chase. Lizards in many families are known to use water bodies as escape routes from potential predators (Pianka and Vitt, *op. cit.*). The majority of the reports on this defensive behavior in neotropical lizards is related to lowland rainforest or flooded-field species, especially semi-aquatic or river-associated lizards (Martins 1991. Faun. Environ. 26:179–190; Ávila-Pires 1995. Zool. Verh. Leiden 299:1–706; Pianka and Vitt, *op. cit.*).

To date, the only known tropidurid for which water-escape has been described is the Amazonian *Uranoscodon superciliosus*. This semi-arboreal species relys largely on crypsis to avoid detection by predators, but when disturbed readily jumps to water, often running across the water surface, but in some cases, diving into the water, and remaining underwater for minutes before emerging (Howland et al. 1990. Can. J. Zool. 68:1366–1373). This represents of the first report of water-based escaped behavior in the genus *Tropidurus*, and a second report for such behavior among tropidurid lizards.

The specimen was deposited in the herpetological collection of the Museu de Zoologia da Universidade de São Paulo, São Paulo, Brasil (MZUSP 98259, José Cassimiro field number JC 1358).

We thank IBAMA for collection permits (10126-1). Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP) provided research grants to JC (process 05/00283-6). Vanessa K. Verdade and Carolina Castro-Mello assisted in the MZUSP, and M. P. Hayes provided editorial suggestions.

XENOSAURUS GRANDIS (Knob-scaled Lizard). **ENDOPARASITES.** *Xenosaurus grandis* is known from the Mexican states of Chiapas, Oaxaca, and Veracruz (Flores Villela and Gerez 1994. Biodiversidad y Conservación en México: Vertebrados, Vegetación y Uso del Suelo. Comision Nacional para el Conocimiento y Uso de la Biodiversidad, Universidad Nacional Autónoma de México, Destricto Federal, 439 pp.). To our knowledge, there are no reports of endoparasites from *X. grandis*. The purpose of this note is to establish an initial helminth list for *X. grandis*.

Eleven *X. grandis* (mean SVL = 110.0 mm ± 17.0 SD, range = 78–130 mm) from Cuautlapan, Veracruz, Mexico (18.8666°N, 97°0166°W, WGS84; elev. 1000–1200 m) collected in 1969, 1970–1972 and deposited in the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California were examined: LACM 75689, 75692–75694, 120051, 120060, 120065, 120071, 120077, 120083, 120086. The body cavity was opened and the digestive tract was removed and examined under a dissecting microscope. Only nematodes were found. These were cleared in a drop of glycerol on a glass slide, coverslipped, and identified using a compound microscope as *Spauligodon xenosauri* infection site: large intestine *(*prevalence = number infected/number examined × 100 = 91%; mean intensity = mean number helminths per infected individual =13.9 ± 12.7 SD. range = 1–36), *Physaloptera* sp. as 3rd stage larvae (the lack of adult specimens makes species identification imprudent, however, *P. retusa* is commonly reported in lizards of Mexico),

infection site: stomach, small intestine (prevalence = 9%, 5.0) and Seuratoidea gen. sp. (larvae in cysts), infection site: stomach wall (prevalence = 36%, mean intensity = 12.8 ± 12.6, range = 2–26). Voucher nematodes were deposited in the United States National Parasite Collection, (USNPC), Beltsville, Maryland as: *Spauligodon xenosauri* (USNPC 101562); *Physaloptera* sp. as 3rd stage larvae (USNPC 101563), and Seuratoidea gen. sp. (USNPC 101564).

Spauligodon xenosauri was described from *Xenosaurus platyceps* from Tamaulipas, Mexico by Bursey et al. (2007. Zootaxa 1501:65–68). *Xenosaurus grandis* is the second host known to harbor it. *Spauligodon xenosauri* is a member of the Oxyuroidea, which infect hosts directly (Anderson 2000. Nematode Parasites of Vertebrates. Their Development and Transmission. CABI Publishing, Oxfordshire, UK, 650 pp.). Infection likely occurs when lizards lick substrate on which eggs are present (see Goldberg and Bursey 1992. J. Parasitol. 78:539–541). *Physaloptera retusa* is a common parasite in lizards of Mexico and North America and requires an insect intermediate host (Bursey et al. 2007. Comp. Parasitol. 74:108–140). Bursey and Goldberg (1991. J. Wildlife Dis. 27:710–715), in a study of *P. retusa* in the lizard *Sceloporus jarrovii*, suggested that approximately 10% of 3rd stage larvae ingested by a host survive to maturity and that those found in the small intestine were dead at time of host capture. Goldberg et al. (1993. Bull. South. California Acad. Sci. 92:43–51) reported hosts for physalopteran larvae; teiid and xenosaurid lizards were absent from that list which suggests that some lizards may not be suitable hosts for this nematode. In this case, these physalopteran larvae should be considered to be artifacts of diet. The life cycles of the Seuratoidea are largely unknown (Anderson 2000, *op. cit.*) but it is thought that insects serve as intermediate hosts. In this study, the cysts were in early granuloma formation perhaps indicating re-encystment of larvae in an inappropriate host. *Xenosaurus grandis* represents a new host record for *Spauligodon xenosauri*, *Physaloptera* sp. (3rd stage) and larvae of Seuratoidea gen. sp.

We thank Christine Thacker (LACM) for permission to examine specimens and Cecilia Nava (Whittier College) for assistance with dissections.

SQUAMATA — SNAKES

BOTHROPS ASPER (Terciopelo). **SCAVENGING BEHAVIOR.** We ecountered a *Bothrops asper* as it scavenged a frog at La Selva Biological Station in Costa Rica (10.4333333ºN, 83.9833333ºW) on 20 April 2008 at dusk (1747 h local time). The *B. asper* (ca. 60 cm long and missing part of its tail) slid onto the cement trail to a dead, rotting frog. The snake grasped the frog in its mouth, dragged it to the leaf litter adjacent to the trail, let go of the frog, then re-approached and consumed it. The frog was decayed beyond identification and attracting flies (Fig. 1).

Scavenging behavior has been documented in 12 species of Crotalinae under field conditions (DeVault and Krochmal 2002, Herpetologica 58:429-436). Sazima and Strüssman (1990. Rev. Brasil. Biol. 50:463–468) suggest that habitat and diet can influence carrion encounter rates. They expect terrestrial snakes with diverse diets to be "occasional" scavengers. As a dietary generalist, the terrestrial *B. asper* meets their prediction (Martins et al. 2002. *In* Schuett et al. [eds.], Biology of the Vipers, pp. 307–328. Eagle Mountain Publishing, Eagle Mountain, Utah). We speculate that scavenging is a prevalent opportunistic foraging strategy for many snakes (A. Solórzano, pers. comm.) that has gone unnoticed due to the difficulty of observing such behaviors under field conditions.

FIG. 1. *Bothrops asper* consuming a scavenged frog at La Selva Biological Station, Costa Rica.

This research was sponsored by the Gates Cambridge Trust.

Submitted by **CORINA J. LOGAN**, University of Cambridge, Department of Experimental Psychology, Cambridge, CB2 3EB, UK (e-mail: itsme@CorinaLogan.com); and **CHRISTOPHER MONTERO**, Ecosystem Services Section, Washington State Department of Natural Resources, Olympia, Washington 98504-7016, USA.

CLELIA SCYTALINA (Mexican Snake Eater). **DIET**. *Clelia scytalina* is a large terrestrial snake whose distribution is apparently unclear and disjunct, occurring at low elevations from southern Mexico to Costa Rica (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. Univ. Chicago Press. Chicago, Illinois. 934 pp.). Natural history of this species is poorly known. In the Los Tuxtlas region of Veracruz, Mexico diet records include frogs and lizards (Pérez-Higareda et al. 2007. Serpientes de la Región de Los Tuxtlas, Veracruz, México. Guía de Identificación Ilustrada. Universidad Nacional Autónoma de México. 189 pp.), but there are no previous records of snakes as prey in this area.

On 17 May 2006 at 1700 h we observed a *C. scytalina* (ca. 120 cm total length) preying on a Parrot Snake (*Leptophis ahaetulla*) of similar length. The event occurred in a dry creek in the tropical rainforest reserve at Los Tuxtlas Field Station (Lote 67, Vigia Hill, 18.5851°N, 95.08055°W, 178 m elev., WGS84). The *C. scytalina* surprised the *L. ahaetulla* at rest, biting its head and starting to

swallow without releasing. When approached to within 3 m, the *C. scytalina* detected our presence, released the prey, and fled into nearby vegetation. The *L. ahaetulla* was still alive but died shortly after the attack.

This is the first report of a *C. scytalina* preying on a *L. ahaetulla* and it suggests that *C. scytalina* is an opportunistic and generalist feeder. This is consistent with other *Clelia* species (Campbell 1998. Amphibians and Reptiles of Northern Guatemala, the Yucatán, and Belize. Univ. Oklahoma Press. 380 pp.; da Costa Pinto and de Lema 2002. Iheringia, Ser. Zool. 92[2]:9–19; Vitt and Vangilder 1983. Amphibia-Reptilia 4:273–296).

We thank Lindley McKay for improving the English language in this note.

CROTALUS ATROX (Western Diamond-backed Rattlesnake). **ADULT PREDATION ON LIZARDS.** The prey of adult *Crotalus atrox* consists of a wide range of mammalian (endothermic) taxa, primarily rodents and lagomorphs. Occasionally, birds are subjugated and consumed (Klauber 1972. Rattlesnakes. Their Habits, Life Histories, and Influence on Mankind. Two vols., 2nd ed. University of California Press, Los Angeles and Berkeley. 1533 pp.; Cundall and Greene 2000. *In* K. Schwenk [ed.], Feeding, Form, Function, and Evolution in Tetrapod Vertebrates, pp. 293–333. Academic Press, San Diego, California; Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Cornell University Press, Ithaca, New York. 870 pp.).

Here, we provide further information on the diet and predatory behavior of adult *C. atrox* from a population in the Sonoran Desert of south-central Arizona. Specifically, we show that adults of a large species of a North American temperate pitviper (Viperidae: Crotalinae) do not exclude relatively small, ectothermic prey from their diet (e.g., Sherbrooke 2003. Introduction to Horned Lizards of North America. University of California Press, Berkeley and Los Angeles. 178 pp.; Nowak et al. 2008. Biol. Rev. 2008: 83:601–620). The individuals of *C. atrox* we discuss were the subjects of a radio-telemetric study in which various aspects of their behavior, physiology, and spatial ecology have been investigated since March 2001 (e.g., Repp and Schuett 2008. Southwest. Nat. 53:108–114).

The present study site, located in Pinal County, is 40 km SSE of Florence and encompasses an area ≈ 3 km^2 at the western perimeter of the Suizo Mountains. This region is ecologically designated as Arizona Upland Desertscrub subdivision (Brown 1994. Biotic Communities of the American Southwest — United States and Mexico. University of Utah Press, Salt Lake City. 342 pp.). Annual precipitation (chiefly rain) patterns are bimodal, with slight to moderate storms occurring during winter and early spring (December–March); the strongest activity occurs from mid- to late summer (early July to mid-September), which is termed the North American monsoon (Brown 1994, *op. cit.*; Phillips and Comus 2000. A Natural History of the Sonoran Desert. The University of California Press, Berkeley and Los Angeles. 628 pp.). The area lacks permanent freestanding water, a common feature of the Sonoran Desert; at the present site, collection of rainwater in surface rocks and soil, as a rule, is transitory, and persists for only minutes to several hours. However, artificial alterations of the habitat (e.g., deep tire tracks in narrow dirt roads) occasionally provide a substantive reservoir for the collection and storage of rainwater, but even under these situations it is ephemeral, especially in summer.

On 10 July 2004, at 2042 h, in an area interfacing bajada (Phillips and Comus 2000, *op. cit.*) and desert flats, an adult male *C. atrox* (CA-32: SVL = 110 mm, TL = 9.5 mm, body mass = 745 g) was radio-tracked and located (Site 21, 822 m elev.) partially coiled beside an adult (SVL ≈100 mm; body mass ≈ 40 g) Regal Horned Lizard, *Phrynosoma solare*. The core body temperature of CA-32 (obtained via an implanted 11.0 g temperature-sensitive

FIG. 1. Predation by adult wild-living Western Diamond-backed Rattlesnakes (*Crotalus atrox*). A) An adult male *C. atrox* (CA-32) beside an adult Regal Horned Lizard (*Phrynosoma solare*) that presumably was envenomated by CA-32. Note the two blood spots (within the yellow ellipses) that most likely resulted from fang punctures of the present snake. Photograph by R. Villa. B) An adult male *C. atrox* (CA-55) beside an adult Desert Spiny Lizard (*Sceloporus magister*) that it presumably subjugated; also, note that the lizard is gaping with its tongue protruding. This lizard was subsequently consumed by CA-55. Photograph by R. Repp.

radio-transmitter; Holohil Systems Ltd, Ontario, Canada) was 32.7ºC. The ambient temperature (1 m above the ground) was 29.0ºC. Cloud cover was ≈ 10%, relative humidity was ≈ 20%, and wind speed was slight (0–5 kph) and intermittent. Upon closer inspection, the *P. solare* was sluggish and had been (presumably) bitten by the present snake; at least two presumptive fang punctures were present on both left and right left sides of the posterior body, and from these wounds oozing dark-colored blood (within yellow ellipses) was detected (Fig. 1A).

From 2042 h to 2111 h, CA-32 was directly facing the lizard and periodically (N = 8 episodes) nudged it, presumably to determine whether it was dead or fully immobilized. During these nudging episodes, the lizard exhibited anti-predator behavior, primarily rearing and directing its head obliquely downward toward CA-32 (see Sherbrooke 2003, *op. cit.*). At 2211 h, the lizard was still alive, and we departed to avoid possible interference. At 2300 h, we re-located CA-32; he was about 10 m from Site 21 and had a food bolus, undoubtedly the *P. solare*.

On 24 July 2004, at 0643 h, 14 days following consumption of the *P. solare*, we radio-tracked male CA-32 and located him (Site 19, 821 m elev.) in bajada; he was coiled 1 m from of an active *Neotoma albigula* midden. An obvious large food bolus (documented via photography) was present; given his location, it was possibly an adult *N. albigula*. His core body temperature was 26.4ºC. The ambient temperature was 25.0ºC and ground temperature in direct sunlight ("hot spot") was 28.0ºC.

On 14 June 2008, from 0630 to 0733 h, in bajada, an adult male *C. atrox* (CA-55: SVL: 99 mm, TL: 80 mm, mass: 687 g) was radio-tracked and located (Site 52, 826 m elev.) beside an adult male (SVL ≈ 140 mm, body mass ≈ 40 g) Desert Spiny Lizard (*Sceloporus magister*). First inspection of the pair revealed that CA-55 was sprawled lengthwise, with the front one-third of his body positioned in a small area of shade in open ground, and his rear two-thirds was beneath a cluster of Triangle Bursage beneath the canopy of a 1.5 m tall Creosote Bush. The snake's chin rested on the tail of the lizard, which was positioned directly in front of and facing away from CA-55. Neither subject was moving; the lizard's eyes were slightly open. Minutes after locating CA-55, his core body temperature was 23.8ºC. The ambient temperature was 25ºC and hot spot was 32ºC. Cloud cover was 0%, relative humidity was ≈ 10%, and wind speed was slight (< 5 kph). Both ambient and hot spot temperatures changed rapidly as sunrise progressed.

At 0648 h, CA-55 slowly crawled lengthwise beside the left side of the lizard, he occasionally rubbed the lizard with his mouth, and then started rubbing his snout on the snout of the lizard. At that point, the lizard flinched and CA-55 slowly withdrew to resume his position behind the lizard. The core body temperature of CA-55 was 26.7ºC. The pair was temporarily left to radio-track another *C. atrox* subject; CA-55 was re-tracked at 0711 h. At that time, CA-55 was on the right side of the lizard, which gaped widely three times, at ≈ 30 sec intervals (Fig. 1B). Following the first gape, the lizard shuddered violently; he also shuddered after the third gape. The third gape and subsequent shudder were the last obvious movements of the lizard. Both subjects were in full sunlight; the body temp of CA-55 was 31.3ºC. The ambient temperature was 29ºC and hot spot was 35ºC.

Because CA-55 appeared disturbed, other subjects of *C. atrox* were subsequently radio-tracked; ca. 20 min later, CA-55 was re-tracked at 0733 h and neither the snake nor the lizard were present at the original site (Site 52). The snake had moved 2 m N of Site 52 into a heavily vegetated arroyo. Inspection revealed that a minor food bolus was present, and it was assumed he had consumed the lizard. Again, CA-55 appeared startled by the observer and quickly coiled in 100% shade under a downed canopy of wolfberry (*Lycium* sp.) branches on the south side of the arroyo. His core body temperature at the conclusion of the observations was 35.5ºC. The ambient temperature was 32ºC and hotspot was 44.5ºC.

In both of the above cases, body masses of the two species of lizards, estimated based on SVL, were ≈ 40 g; this represents 5% (CA-32, 745 g) and 6% (CA-55, 687 g) of the body masses of the respective snakes. Moreover, the resultant food boluses, as expected, were not highly discernible compared to larger prey such as commonly consumed mammals (e.g., ground squirrels, woodrats); owing to their size, it is likely that the present food items would have been overlooked under most situations. Hence, this suggests that predation attempts and feeding frequency in certain large rattlesnakes (and other vipers) are underestimated (Nowak et al. 2008, *op. cit.*). Also, we show that adult *C. atrox* can successfully feed on adult horned lizards (*Phrynosoma* spp.) without (apparent) subsequent injury (see comments by Sherbrooke 2003, *op. cit.*).

Support for our field studies at the Suizo Mountains is from Arizona State University, Zoo Atlanta, Georgia State University, and David L. Hardy, Sr. Since 2001, many individuals provided assistance in the field, but most noteworthy are Hans-Werner Herrmann and Ryan Sawby. Also, Ryan Sawby provided invaluable assistance with photography and identification of plant and invertebrate taxa. We thank Emory Schuett, Robert Villa, and Annamarie Saenger for their help in making observations on the present *C. atrox* and *P. solare*. This study was approved by the animal care and use committee (IACUC) of Arizona State University (98-429R), and appropriate scientific permits were obtained from the Arizona Game and Fish Department.

SCHUETT**, Department of Biology and Center for Behavioral Neuroscience, Georgia State University, 33 Gilmer Street, S. E., Unit 8, Atlanta, Georgia 30303-3088, USA (e-mail: biogws@langate.gsu.edu, or gwschuett@yahoo.com).

EPICRATES CENCHRIA (Brazilian Rainbow Boa). **DIET.** On 27 February 2008, at 2350 h, during a radiotracking study at Floresta River (22.5275°S, 42.5516667°W), Reserva Botânica Águas Claras, Silva Jardim, Brazil, we located a female (280 g) radio-collared Neotropical Water Rat (*Nectomys squamipes*) inside an *Epicrates cenchria* (ca. 2 m total length). The snake was <1 m from the river's edge and active. We observed it again two days later in a shelter at the base of a large tree (3.55 m perimeter at breast height), at 5.1 m above the river level and 0.5 m from the river. This shelter had three openings, the measures were: 16×14×66; 20×7×56 and 22×18×49 cm (biggest diameter, perpendicular diameter and depth, respectively). The radiotransmitter was found one month later in what appeared to be regurgitations of the snake

in the same shelter.

Epicrates cenchria is widely distributed in Central and South America, from Costa Rica to Argentina (Tolson 1987. Occas. Pap. Mus. Zool., Univ. Michigan 715:1–68; Vanzolini et al. 1980. Répteis das Caatingas. Academia Brasileira de Ciências, Rio de Janeiro. 161 pp). All *Epicrates* are nocturnal and most eat exclusively endotherms, with most diet records consisting of bats and rodents (*Mus, Rattus*) (Nellis et al. 1983. J. Herpetol. 17:413–417). To the best of our knowledge, this is the first record of *E. cenchria* predation on *N. squamipes*, the largest and most adapted to semi-aquatic life among sigmodontine rodents.

We thank Idea Wild for equipment, Fundação o Boticário de Proteção à Natureza, CNPq and PIBIC/CNPq for financial support. In addition, we thank our colleagues in the Laboratório de Ecologia e Conservação de Populações for assistance.

FARANCIA ERYTROGRAMMA (Rainbow Snake). **HABITAT**. *Farancia erytrogramma* is a secretive, nocturnal species occurring in southeastern USA (Gibbons and Dorcas 2005. Snakes of the Southeast. University of Georgia Press, Athens, Georgia. 253 pp.). In North Carolina, this species can be found throughout the coastal plain (Palmer and Braswell 1994. Reptiles of North Carolina. University of North Carolina Press, Chapel Hill, North Carolina. 412 pp.) and usually inhabits clear, fluvial water systems with low turbidity, neutral pH, and standing vegetation for cover (Neill 1964. Amer. Midl. Nat. 71:257–295). However, past research revealed this species can occur in standing freshwater habitats, such as Carolina bays (Gibbons et al. 1977. Herpetologica 33:276–281).

During a study of the reptile and amphibian community at Bull Neck Swamp (35.96667°N, 076.41667°W), one *F. erytrogramma* was captured with an aquatic funnel trap. Bull Neck Swamp (BNS) is a 2428-ha pocosin wetland located 28 km E of Plymouth, North Carolina, USA, and is managed by the Fisheries and Wildlife Sciences Program at North Carolina State University.

The highly turbid canals of tannic flows and thick bottom debris that meander throughout BNS were an unexpected habitat to discover *F. erytrogramma*, which prefer clear, moving water (Neill 1964, *op. cit.*). Neill (*op. cit*.) maintained that consistent temperatures of stream habitats were important for thermoregulation. Also, fluvial habitats provide cover for American Eels (*Anguilla rostrata*) and Neill (*op. cit*.) suggested the predominant diet on *A. rostrata* further supported the constraint of *F. erytrogramma* to these habitats. However, steep, sandy canal banks prevented the growth of standing vegetation, which likely reduced refuge and staging habitats for nocturnal foraging. Further, Beaver (*Castor canadensis*) dams reduced what little flow existed in some canals to standing quagmires more representative of the habitat selected by Eastern Mudsnakes (*Farancia abacura*; Neill 1964, *op. cit.*). Interestingly, one *A. rostrata* was observed near BNS, but none was captured within the swamp. It is possible that Rainbow Snakes leave bordering fluvial habitats in pursuit of young eels that wandered into canals and swamp habitats.

Capturing such a secretive and uncommon species as *F. erytrogramma* in unexpected habitat encourages consideration of their delicate ecological niche. Declining population indices for American Eels along the eastern United States are attributed to overfishing, parasitism, habitat loss, pollution, and changes in major currents related to climate change (Hightower and Nesnow 2006. Southeast. Nat. 5:693–710). Eel declines could negatively impact population sizes and distributions of Rainbow Snakes, especially in inland areas. We believe future studies based on confirmed Rainbow Snake occurrences from museum records or North Carolina GAP data could better delineate the range within North Carolina. Additionally, sampling for American Eels to determine their population status and distribution in North Carolina could augment population and distribution data for Rainbow Snakes.

We thank A. Braswell, J. Jensen, and P. Moler for comments on earlier drafts of this manuscript.

Submitted by **STAN J. HUTCHENS** (e-mail: stanhutchens@gmail.com) and **CHRISTOPHER S. DEPERNO**, (e-mail: chris_deperno@ncsu.edu), Fisheries and Wildlife Program, North Carolina State University, 110 Brooks Ave., Raleigh, North Carolina 27607, USA.

HELMINTHOPHIS FRONTALIS (Northern Antsnake). **FEEDING BEHAVIOR**. Fossorial blind worm snakes are frequently found under debris in lowland moist and premontane forests in Costa Rica and Panama (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago, Illinois. 934 pp.). The habits of these snakes are nearly unknown because of their burrowing and secretive lifestyle, though it is known that the diet of *Helminthophis frontalis* (Anomalepididae) consists of ants, termites and their larvae (Solórzano 2004. Serpientes de Costa Rica. Instituto Nacional de Biodiversidad (INBio). Heredia, Costa Rica. 792 pp.). How blind worm snakes prey upon ants and termites without being attacked by these colonial insects has not yet been described.

Leptotyphlops dulcis (Leptotyphlopidae), another blind burrowing snake that feeds on termites, preys on immature stages of colonial insects (e.g., ants and termites), apparently without being attacked. This blind snake covers itself with feces and a viscous odoriferous liquid that is secreted by the cloaca prior to crawling into the colony. This substance repels the ants and prevents their attack (Gehlbach et al. 1968. Bioscience 18:784–785). This information is missing for most fossorial blind worm snakes, though there are a few reports of some species using this strategy (Zug et al. 2001. Herpetology: An Introductory Biology of Amphibians and Reptiles. 2nd ed. Academic Press. California,. 630 pp.).

On 21 July 2004, we observed a *Helminthophis frontalis* entering an ant colony in San José City, Costa Rica. As the snake attempted

to enter, it was immediately attacked and expelled by the ants. The attack eventually ceased and the snake was able to enter the colony and remain inside, preying upon adult ants and their larvae. After 5 minutes, we removed the snake from the colony and observed that it was covered by an odoriferous viscous substance. Presumably such material repelled the ants and protected the snake from being attacked. A few minutes later, we placed the snake back into the colony and noted that the substance was produced from the cloaca and seemed to allow the snake to feed, undisturbed by ants.

Despite the phylogenetic association of the families Leptotyphlopidae and Anomalepididae, this specialized feeding-related behavior has not been reported for species of the latter (Savage, *op. cit*.).

Submitted by **BRANKO HILJE**, Department of Biology, University of Puerto Rico, Río Piedras P.O. Box 23360, San Juan, Puerto Rico, 00931-3360 (e-mail: bhilje@yahoo.com); and **MARIEL YGLESIAS**, Centro Agronómico Tropical de Investigación y Enseñanza (CATIE), Turrialba, Costa Rica (e-mail: mariel_yglesias@yahoo.es).

LEPTODEIRA SEPTENTRIONALIS (Cat-eyed Snake). **PREY.** Many neotropical snakes feed primarily on anurans (Vitt 1983. Herpetologica 39:52–66) but information regarding their individual prey species is scarce. On 15 November 2004 at 21 h, in the Refugio de Vida Silvestre, Golfito (Costa Rica, Puntarenas Province, 8.65°N, 83.18°W, ca. 5 m elev.), I observed an adult *Leptodeira septentrionalis* swallowing a *Leptodactylus bolivianus* (Fig. 1). The frog was ingested head first. *L. bolivianus* represents a hitherto unreported prey item for *L. septentrionalis.*

FIG. 1. *Leptodeira septentrionalis* swallowing a *Leptodactylus bolivianus.*

Submitted by **DAVID MATTHIAS DEHLING**, Department of Ecology, Animal Ecology, Faculty of Biology, Philipps-University Marburg, Karl-von-Frisch-Straße 8, D-35032 Marburg, Germany; e-mail: Dehling@students.uni-marburg.de

LEPTOPHIS AHAETULLA PRAESTANS (Green Parrot Snake). **PREDATION ATTEMPT.** *Leptophis ahaetulla* is a large, diurnal, and arboreal species, occurring in different vegetation types from southern Mexico to Brazil and Argentina (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. Univ. Chicago Press. Chicago, Illinois. 934 pp.). It has been reported that *L. ahaetulla* forages in trees and shrubs for sleeping or resting frogs, and to a lesser extent, arboreal lizards (Oliver 1948. Bull. Am. Mus. Nat. Hist. 92:157–280; Pérez-Higareda et al. 2007. Serpientes de la Región de Los Tuxtlas, Veracruz, México. Guía de Identificación Ilustrada. Universidad Nacional Autónoma de México. 189 pp.). There are no reports for prey items for *L. ahaetulla* in Mexico, so here we record a feeding attempt observed in Veracuz.

On 18 April 2007 at ca. 1000 h on bare soil adjacent to buildings belonging to Los Tuxtlas Tropical Biology Station (18.5851°N, 95.0752°W, 119 m elev., WGS84), we observed a *L. ahaetulla* (ca. 150 cm total length) feeding on a Baudin's Treefrog (*Smilisca baudini*, ca. 60 mm snout–vent length). The snake held the frog in its mouth for a minute but when we approached to a distance of 2 m, the snake released the frog and fled. The frog was alive though motionless, and died some minutes later.

Frogs (especially hylids) have been recorded as the main food items for *L. ahaetulla* elsewhere in its range (e.g., Campbell 1998. Amphibians and Reptiles of Northern Guatemala, the Yucatán, and Belize. Univ. Oklahoma Press. 380 pp.; De Albuquerque and Di-Bernardo 2005. Herpetol. Rev. 36:325; Lopez et al. 2003 Herpetol. Rev. 34:68–69). Other reported prey for *L. ahaetulla* are birds, bird's eggs, and grasshoppers (Oliver 1948, *op. cit;* Lopez et al., *op. cit*).

We thank Lindley McKay for improving the English language in this note.

LIOPHIS VITTI (NCN). **DIET**. The colubrid snake *Liophis vitti* is known from the western Andean slopes in northern Ecuador at elevations between 1070–1650 m (Dixon 2000. Copeia 2000:482–490). A specimen collected "one meter high on leaf in forest at night" is all the natural history data available in the literature for this species (Dixon, *op. cit*.). On 24 February 2009, we collected a male *L. vitti* (QCAZ 8708, SVL = 368 mm, TL = 110 mm) in northwestern Ecuador, Carchi Province, Chilmá Bajo (0.8647222°N, 78.0497222°W, 2071 m elev.). This specimen had recently eaten, as indicated by an anterior swelling at about one fourth its SVL. The forced-out prey was a specimen of an undescribed species of the bufonid toad *Osornophryne* (QCAZ 40028, SVL = 30.4 mm). No records of *Osornophryne* are known from this locality. Moreover, this is the first record of predation of *Osornophryne* by any vertebrate. Both specimens are deposited in the

herpetological collection of Museo de Zoología QCAZ, Pontificia Universidad Católica del Ecuador.

MASTIGODRYAS MELANOLOMUS (NCN). **PREY.** Information on the trophic ecology and individual prey species of certain tropical snakes is scarce. *Mastigodryas melanolomus* is a moderately-sized colubrid snake that forages on the ground and preys on lizards, small snakes, reptile eggs, nesting birds, and small mammals (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago, 994 pp.). On 14 October 2004 at 1530 h, in the Reserva Biológica Hitoy Cerere (Costa Rica, Limón Province, 9.66°N, 83.03°W, ca. 200 m elev.), I observed a *M. melanolomus* with a total length of about 1.2 m that had entered a hole in the ground up to about the anterior third of its body. When it reappeared, it was holding an adult *Ameiva festiva* in its mouth (Fig. 1). Although *M. melanolomus* is known to prey on other species of *Ameiva* (Seib 1984. J. Herpetol. 18:412–420), *A. festiva* has not yet been reported as a prey item of *M. melanolomus*.

FIG. 1. *Mastigodryas melanolomus* preying on *Ameiva festiva*.

Submitted by **DAVID MATTHIAS DEHLING**, Department of Ecology, Animal Ecology, Faculty of Biology, Philipps-University Marburg, Karl-von-Frisch-Straße 8, D-35032 Marburg, Germany; e-mail: Dehling@students.uni-marburg.de.

OXYRHOPUS CLATHRATUS (NCN) **PREY.** Species of *Oxyrhopus* are known to prey on small lizards (Bernarde and Machado 2000. Herpetol. Rev. 31:247–248.). On 2 September 2004, during fieldwork in Teresópolis municipality, Rio de Janeiro State, southeastern Brazil (22.448442°S, 42.983542°W), we collected a recently deceased juvenile *Oxyrhopus clathratus* (312 mm total length), that contained an adult *Placosoma cordyline* (153.3 mm total length). The cause of death of the snake is unknown. This is the first report of predation of *P. cordyline* by *O. clathratus*. Both specimens are deposited in the herpetological collection of the Universidade Federal do Estado do Rio de Janeiro, Brazil, under the accession numbers ZUFRJ 1650 (*Oxyrhopus clathratus*) and 1651 (*Placosoma cordyline*).

We thank Universidade Federal do Estado do Rio de Janeiro for transport logistics, and Henrique C. Costa and Paulo Sérgio Bernarde for suggestions on the manuscript.

OXYRHOPUS GUIBEI (False Coralsnake). **DIET.** *Oxyrhopus guibei* is a terrestrial, crepuscular-nocturnal pseudoboine snake in southeastern Brazil (Sazima and Abe 1991. Stud. Neotr. Fauna Environ. 26:159–164). Reported prey items include rodents, lizards (Andrade and Silvano 1996. Rev. Bras. Zool. 13[1]:143–150; França et al. 2008. Copeia 2008:23–38), and birds (Sazima and Abe 1991. Stud. Neotr. Fauna Environ. 26:159–164).

We dissected 17 specimens of *O. guibei* from the vicinity of the Irapé Power Plant (16.75°S; 42.53°W), Minas Gerais state, Brazil, collected between February 2004 and July 2006 during a faunal monitoring program. We found 10 prey items in the stomachs of three males (total length: 404, 629, and 811 mm), two females (total length: 599 and 1016 mm), and three juveniles (total length: 289, 306, and 363 mm). Prey consisted of rodents (70%) and lizards (30%). Nonetheless, one adult female *O. guibei* (1016 mm total length) had digested parts of an individual *Oxymycterus* sp. (Cricetidae) in its stomach. This snake also contained 10 vitellogenic follicles (> 10 mm, following Pizzatto and Marques 2002. Amphibia-Reptilia 4:495–504). Rodents of the genus *Oxymycterus* have semi-fossorial habits and are endemic to South America (Hershkovitz 1994. Fieldiana Zool. 79:1–43; Câmara and Murta 2003. Mamíferos da Serra do Cipó. Ed. PUC Minas. Belo Horizonte. 129 pp.). The rodent body parts had a volume of 5478.7 mm^3 and seemed derived from an adult individual. To our knowledge this is the first record of the semi-fossorial rodent *Oxymycterus* as a food item of *O. guibei*. Furthermore, another two species of rodents belonging to the Cricetidae family were found: four *Necromys lasiurus* in three specimens and two *Calomys tener* in one. Three unidentified tails of lizards were found in three juvenile specimens.

Representative specimens are deposited in the Herpetological Laboratory of Museu de Ciências Naturais of Pontifícia Universidade Católica de Minas, Minas Gerais, Brazil (MCNR 915, 1718, 1847, 1923, 2511). We thank Sônia A. Talamoni for identifying the rodents and FAPEMIG for financial support to LBN.

Submitted by **LAURA RODRIGUES VIEIRA DE ALENCAR**, Departamento de Ecologia, Instituto de Biociências, Universidade de São Paulo, Rua do Matão, Travessa 14, Cidade Universitária, São Paulo, SP, Brazil, CEP 05508-090 (e-mail: laura.alencar@globo.com); **CONRADO A. PHILODRYAS CHAMISSONIS (Long-tailed Snake) and ***LIOLAEMUS NITIDUS*****. PREDATION DETERMINED BY PIT TAG**. As part of a multi-species capture-recapture study in central Chile (31.9861°S, 71.1696167°W, 820 m elev., datum Prov SudAm 56) during October 2007, we collected a *Philodryas chamissonis* (68 cm total length, 24 g) that contained a secondarily-ingested PIT tag in its stomach. The PIT tag originally had been placed in a juvenile *Liolaemus nitidus* (5.0 cm SVL, 4.6 g) in December 2006 (10 months earlier). Thus, the minimum prey/predator ratio is 19.2%, exceeding the mean value of 7.7 ± 3.1% reported by Greene and Jaksic (1992. Rev. Chil. Hist. Nat. Santiago, Chile 65:485–493) for museum specimens of *P. chamissonis*. Our observation suggests the potential utility of PIT tags in long-term studies of predation.

RHINOCHEILUS LECONTEI (Long-nosed Snake). **CANNIBALISM.** The diet of *Rhinocheilus lecontei* consists mainly of lizards, small mammals, and squamate eggs (Rodríguez-Robles et al. 1999. J. Herpetol. 33:87–92; Rodríguez-Robles and Greene 1999. J. Zool. Lond. 248:489–499). Although general references to predation on snakes have appeared (e.g., Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque. 431 pp.; Stebbins 2003. A Field Guide to Western Reptiles and Amphibians, 3rd ed., revised. Houghton Mifflin Co., Boston, Massachusetts. 533 pp.; Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History. Univ. Texas Press, Austin. 437 pp.), specific reports are lacking and thus it is unclear if *R. lecontei* preys on snakes in the wild. Klauber (1941. Trans. San Diego Soc. Nat. Hist. 9[29]:289–332) reported feeding on *Chionactis occipitalis* in captivity. Here I document an instance of predation on a juvenile conspecific.

FIG. 1. Adult *Rhinocheilus lecontei* ingesting a juvenile conspecific, Alameda Co., California.

On 17 May 2009 at 2307 h, I observed an adult *R. lecontei* (estimated total length 90 cm) ingesting a juvenile conspecific (ca. 32 cm TL) (Fig. 1). Although ingestion had commenced before my arrival, the sequence I observed was completed in ca. 2 minutes. The smaller snake did not display any obvious injuries. This observation took place 24 km by air SE of Livermore, Alameda Co., California, USA.

Submitted by **CHAD M. LANE**, 426 Swallow Ct, Manteca, California 95336, USA; e-mail: ChadMLane@aol.com.

THAMNOPHIS ELEGANS VAGRANS (Wandering Gartersnake). **DEFENSIVE BEHAVIOR**. Several species of snakes have been observed to enlarge or triangulate the head as a defensive response to a predator (Greene 1988. *In* C. Gans and R. B. Huey [eds], Biology of the Reptilia, Volume 16, Ecology B, pp. 1–152. Alan R. Liss, New York). In June 2007, I observed this behavior as a defensive response in three specimens of *Thamnophis elegans vagrans* (ca. 45 cm total length) in a residential area of Springville, Utah, USA (40.1529°N, 111.5960°W). Sexes were not determined.

Defensive responses in the snakes were elicited by a peck on the head by a nest-guarding American Robin (*Turdus migratorius*). The nest was located 1.75 m above ground in a cherry tree (*Prunus cerasus*). The robin attacked up to 4.6 m from its nest. The original observation occurred with no manipulation on my part. However, after the initial observation, I captured two other *T. e. vagrans* within 200 m of the nest site and placed them individually under the same robin nest. The bird responded in the same manner to these new snakes (i.e., flying from nest to ground and pecking at the snake's head). Upon being attacked, the snakes quickly coiled and exhibited head triangulation, accompanied by aggressive posturing, i.e. in a stance poised to strike, and repeated striking with mouth open. Once the snakes exhibited this defensive behavior, attacks by the bird ceased.

Head triangulation as a defensive response has been documented for many colubrid species (Greene 1988, *op. cit.*), and has apparently evolved independently multiple times (Young et al. 1999. J. Zool., Lond. 248:169–177). However, to the best of my knowledge this is the first report of head triangulation in *Thamnophis*. Werner

(1983. Israel J. Zool. 32:205–228) postulated that this behavior can be classified as Batesian mimicry of sympatric venomous snakes. *Crotalus viridis* (Western Rattlesnake) is broadly sympatric with *T. e. vagrans* over most of its range (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin Co., Boston, Massachusetts. 533 pp.).

Special thanks to Caleb, Shiloh, Jubal, Micah, and Cyrus Rasmussen for help in catching and observing the snakes.

Submitted by **JOSH E. RASMUSSEN**, Department of Biology, Brigham Young University, Provo, Utah 84663, USA; e-mail: josh_rasmussen@byu.edu.

Cover Images for *Herpetological Review*

We are looking for photographic images to appear on future covers of *HR*. To be considered, preferred images should have the following qualities:

- Should be technically superior photographs (e.g., composition, lighting, etc., should be excellent; subject must be in focus).
- Should be taken in vertical format, or, if in landscape format, permit cropping to achieve a vertical orientation.
- Should be based on film or digital media; if the latter, the native resolution must be sufficiently high to permit cropping and/or enlargement to print publication quality (many "point-and-shoot" digital cameras do not produce image files with sufficient resolution for print publication).
- Preference will be given to images that depict poorly known species. These could include recently described taxa or species for which a color illustration has never been published.
- Preference will be given to images that communicate some aspect of the biology of the organism (e.g., predation, feeding, courtship, crypsis).

Images for consideration should be submitted as low-resolution jpg or pdf files. Do not send full resolution images via email. All submissions or questions should be directed to the Editor (herpreview@gmail.com).

GEOGRAPHIC DISTRIBUTION

Instructions for contributors to Geographic Distribution appear in Volume 40, Number 1 (March 2009, p. 106). Please note that the responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extension reports unless a thorough literature review has been completed.

CAUDATA – SALAMANDERS

AMBYSTOMA MACULATUM (Spotted Salamander). USA: ARKANSAS: Searcy Co.: Off AR 14, ca. 2 km down Ramblewood Trail in a small pool of water (36.0568°N, 92.6044°W; WGS 84). 20 February 2009. M. B. Connior. Verified by S. E. Trauth. Arkansas State University Museum of Zoology Herpetology Collection (ASUMZ 31298). This adult male is a new county record filling a distributional hiatus between previous records in Marion, Stone, Van Buren, and Newton counties in northern Arkansas (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. University of Arkansas Press, Fayetteville. 421 pp.).

Submitted by **MATTHEW B. CONNIOR,** Department of Biological Sciences, Arkansas State University, P.O. Box 599, State University, Arkansas 72467, USA; e-mail: matthew.connior@smail.astate.edu.

AMBYSTOMA MACULATUM (Spotted Salamander). USA: TENNESSEE: Van Buren Co.: Ephemeral pond near entrance to paved field just prior to Fall Creek Falls Inn parking lot (35.6561ºN, 85.3711ºW: datum NAD 27). Matthew L. Brown. Verified by A. Floyd Scott. One adult located, photographed and catalogued at Austin Peay State University Center for Field Biology (APSU 18953). First county record (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp. Internet version [http://www.apsu.edu/amatlas] contains links to information regarding Tennessee distribution of amphibians recorded since 1996; accessed 05 February 2009). Extends range approximately 15 km SW of nearest recorded occurrence.

Submitted by **MATTHEW L. BROWN**, Fall Creek Falls State Park, Pikeville, Tennessee 37367, USA; e-mail: matthew.brown@state.tn.us.

AMBYSTOMA TIGRINUM (Eastern Tiger Salamander). USA: OKLAHOMA: McCurtain Co.: 1.2 km E Pollard Community on Ferguson Road (33.47640°N, 94.42591°W; WGS84). 18 March 2009. J. Ferguson. Verified by S. E. Trauth. Arkansas State University Herpetological Museum (ASUMZ photographic voucher 31306). First record for the county (Oklahoma Biological Survey DOKARRS Search; http://www.biosurvey.ou.edu/dbsrch/dokalist.php); adult male with swollen vent found crossing gravel road in early morning.

Numerous *A. tigrinum* from the state are in the collection of the Sam Noble Oklahoma Museum of Natural History of Oklahoma; one specimen (SNOMNH 25011) is from adjacent Pushmataha Co. The species occurs immediately southward across the Red River in Red River Co., Texas (Dixon 2000. Amphibians and Reptiles of Texas, 2nd ed. Texas A&M University Press, College Station, Texas. 421 pp.). However, *A. t. tigrinum* has not yet been reported

north of the Red River from any counties along the southwestern tier in Arkansas (Trauth et al. 2004. Amphibians and Reptiles of Arkansas. Univ. Arkansas Press, Fayetteville. 421 pp.).

Submitted by **CHRIS T. McALLISTER**, RapidWrite, 102 Brown Street, Hot Springs National Park, Arkansas 71913, USA (e-mail: drctmcallister@aol.com); **HENRY W. CRYPTOBRANCHUS ALLEGANIENSIS (Hellbender). USA: TENNESSEE: Rutherford Co.: J. Percy Priest Reservoir, Spring Creek branch (36.0353ºN, 86.4467ºW; NAD83). 20 April 1990. Mark Hodge. Verified by M. L. Niemiller. An adult female gravely injured by a fisherman's attempts to retrieve baited hook from stomach. Deposited in the Herpetology Collection at Middle Tennessee State University (MTSU 422C). First record for county and for the Stones River watershed, ca. 60 km SE of historical record for the Cumberland River in Davidson Co., Tennessee (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp. Internet version [http://www.apsu.edu/amatlas] contains links to information regarding Tennessee distribution of amphibians recorded since 1996; accessed 03 March 2009).

Submitted by **BRIAN T. MILLER**, Department of Biology, Middle Tennessee State University, Murfreesboro, Tennessee 37132, USA (e-mail: bmiller@mtsu.edu); and **JOYCE L. MILLER**, MIMIC, Middle Tennessee State University, Murfreesboro, Tennessee 37132, USA (e-mail: jlmiller@mtsu.edu).

NOTOPHTHALMUS VIRIDESCENS LOUISIANENSIS (Central Newt). USA: ARKANSAS: Dallas Co.: 5.6 km S Sparkman off St. Hwy 7 at Brushy Creek (Sec. 15, T10S, R17W). 07 May 1986. Henry W. Robison. Verified by S. E. Trauth. Arkansas State University Herpetological Museum (ASUMZ 30829). New county record filling a distributional gap between Clark and Cleveland counties (Trauth et al. 2004. Amphibians and Reptiles of Arkansas. Univ. Arkansas Press, Fayetteville. 421 pp.), and leaving only Lafayette Co. without documentation of *N. v. louisianensis* for all of south Arkansas.

Submitted by **HENRY W. ROBISON**, Department of Biology, Southern Arkansas University, Magnolia, Arkansas 71754, USA (e-mail: hwrobison@saumag.edu); and **CHRIS T. McALLISTER**, Department of Physical and Life Sciences, Chadron State College, Chadron, Nebraska 69337, USA (e-mail: cmcallister@csc.edu).

PSEUDOTRITON MONTANUS (Mud Salamander) USA: ALABAMA: Bibb Co.: 18.0 km WSW of Eoline (32.90679ºN, 87.39313ºW, WGS84). 14 November 2008. Heather Cunningham, Walter H. Smith, and Joseph J. Apodaca. Verified by Leslie J. Rissler. University of Alabama Herpetological Collection (UAHC 16175, 16178). Two adult *Pseudotriton montanus* were found under leaf litter along the margin of a beaver-impounded wetland in the Talladega National Forest (Oakmulgee District) of west-central Alabama. This wetland was located along an unnamed tributary of Fivemile Creek in a mixed bottomland hardwood/yellow pine forest, with extensive canopy cover. This site is located ca. 60 km outside of the currently accepted range for *P. montanus* and is 94 km from the nearest catalogued voucher for the species (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, DC). The presence of a disjunct portion of the range of *P. montanus* in eastern Mississippi (Petranka, *op. cit*.) presents several possible implications for this new locality. It is possible that the contiguous range of *P. montanus* extends westward at least to the Alabama locality described here. Because this Alabama locality is centered between the recognized contiguous range and the disjunct Mississippi population it may also be possible that the range of *P. montanus* extends westward across the Gulf Coastal Plain to encompass the Mississippi population.

Submitted by **HEATHER CUNNINGHAM**, **WALTER H. SMITH**, and **JOSEPH J. APODACA**, Department of Biological Sciences, Ecology, Evolution, and Systematics Section, Box 870345, University of Alabama, Tuscaloosa, Alabama 35487, USA.

TARICHA GRANULOSA (Rough-skinned Newt) USA: CALIFORNIA: Butte Co.: North Fork Feather River, ca. 1.4 mi. upstream from Poe Powerhouse, west bank (39.72273ºN, 121.47105ºW; datum: WGS 84); 286 m elev.; adult (California Academy of Sciences 241781) captured on 13 March 2008 at 1300 h underwater in a pool tail-out; water temperature 21.5ºC; K. D. Wiseman. Verified by Ricka Stoelting. A second specimen (CAS 234628) was found at 39.80197ºN, 121.44695ºW, 404 m elev. on 15 June 2006. Specimen verified by Jens Vindum. CAS 241781 extends the known distribution of *T. granulosa* in the Sierra Nevada of California ca. 7.7 miles SE, while CAS 234628 extends the distribution ca. 9.1 miles E of specimens previously regarded as the southern extent of their distribution in the Sierra Nevada (MVZ 56784–56798; Hayes and Cliff 1982. Herpetol. Rev. 13[3]:85–87; Koo and Vindum 1999. Amphibians and Reptiles of the Plumas National Forest: Historical Collections and California Academy of Sciences 1998 and 1999 Surveys; Koo et al. 2004. Results of 02-CS-11050650-029, the California Academy of Sciences Survey: Amphibians and Reptiles of the Lassen National Forest). These specimens are also significant as they document *T.*

granulosa occupying the North Fork Feather River watershed, a distinct watershed from the West Branch Feather River watershed, previously considered the southern extent of the species range in the Sierra Nevada of California (Hayes and Cliff, *op. cit.*). *Taricha granulosa* is found in sympatry with *Taricha torosa* at localities provided herein.

Submitted by **KEVIN D. WISEMAN,** Garcia and Associates (GANDA), 2601 Mission Street, Suite 600, San Francisco, California 94110, USA; Department of Herpetology, California Academy of Sciences, 55 Music Concourse Drive, Golden Gate Park, San Francisco, California 94118, USA; e-mail: kwiseman@garciaandassociates.com.

ANURA – FROGS

AGALYCHNIS SPURELLI (Gliding Treefrog). COSTA RICA: SAN JOSE: Distrito Carara, El Sur de Turrubares, (9.4339ºN, 84.34038ºW; WGS84), 385 m elev. 19 August 2006. A. Vega, J. M. Robertson, and G. Chaves. Verified by Federico Bolaños. Museum of Zoology, Universidad de Costa Rica, San Jose (UCR 19214). New province record and a 114 km NW range extension from the closest previous record at Palmar Norte, Puntarenas, expanding its distribution along the Pacific versant on the Cordillera de Talamanca (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. Univ. Chicago Press, Chicago, Illinois. xx + 934 pp.). The frog was calling from a tree-lined temporary pool in an agricultural field once covered by lowland rainforest, along with a large breeding congregation of *Agalychnis callidryas*.

Submitted by **ANDRES VEGA**, AMBICOR, 400 E., 75 S., 75 E. de la Municipalidad de Tibas, Tibas, Costa Rica (e-mail: avegak@hotmail.com); **JEANNE M. ROBERTSON**, Department of Ecology and Evolutionary Biology, Cornell University, Ithaca, New York 14853, USA (e-mail: jmr79@cornell.edu); and **GERARDO CHAVES**, Museum of Zoology, University of Costa Rica, San Jose (e-mail: cachi@biologia.ucr.ac.cr).

ANAXYRUS DEBILIS DEBILIS (Eastern Green Toad). USA: TEXAS: Stephens Co.: N of Eolian (32.68165ºN, 99.03378ºW; 370 m elev.). 21 March 2009. J. Meik, J. Streicher, and S. Schaack. Verified by C. J. Franklin. University of Texas at Arlington, UTA A-59175. Collected under a rock adjacent to a gravel road in Post Oak savannah. First known county record of the species, which fills a distributional gap in north-central Texas (Dixon 2000. Amphibians and Reptiles of Texas. 2nd ed. Texas A&M Univ. Press, College Station). Collected under Texas Parks and Wildlife permit number SPR-0707-1387.

Submitted by **JEFFREY W. STREICHER** (e-mail: e-mail: streicher@uta.edu.), **JESSE M. MEIK**, and **SARAH SCHAACK**, Department of Biology, The University of Texas at Arlington, Arlington, Texas 76019, USA.

HYLA CINEREA (Green Treefrog). USA: TENNESSEE: Van Buren Co.: Fall Creek Falls State Park Golf Course Pond (35.65ºN, 85.3606ºW: datum NAD 27). 11 July 2008. Matthew L. Brown and Leigh Ann Brown. Verified by A. Floyd Scott. One adult photographed and catalogued at Austin Peay State University Center for Field Biology (APSU 19959). Only specimen found in park. Calls have been audible for at least two years at the Fall Creek Falls State Park Golf Course pond. Possible introduction, 62.2 km N of nearest recorded occurrence (Miller et al. 2007. Herpetol. Rev. 38:97). First county record (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp. Internet version [http://www.apsu.edu/amatlas] contains links to information regarding Tennessee distribution of amphibians recorded since 1996; accessed 17 January 2009).

Submitted by **MATTHEW L. BROWN**, Fall Creek Falls State Park, Pikeville, Tennessee 37367, USA; e-mail: matthew.brown@state.tn.us.

GASTROPHRYNE CAROLINENSIS (Eastern Narrow-mouthed Toad). USA: ARKANSAS: Boone Co.: 3.2 km SE of Harrison off US 65 (36.122014°N, 93.039479°N; NAD83). 10 June 1995. H. W. Robison. Verified by S. E. Trauth. Arkansas State University Herpetological Museum (ASUMZ 31305). New county record partially filling a distributional hiatus in northern Arkansas between Benton and Marion counties (Trauth et al. 2004. Amphibians and Reptiles of Arkansas. Univ. Arkansas Press, Fayetteville. 421 pp.). This frog has now been documented in 69 of 75 (92%) Arkansas counties.

Submitted by **CHRIS T. McALLISTER**, RapidWrite, 102 Brown Street, Hot Springs National Park, Arkansas 71913, USA (e-mail: drcmcallister@aol.com); and **HENRY W. ROBISON**, Department of Biology, Southern Arkansas University, Magnolia, Arkansas 71754, USA (e-mail: hwrobison@suddenlink.net).

KALOULA PULCHRA (Painted Bull Frog): MALAYSIA: SARAWAK: MIRI DIVISION: Kuala Lutong, nr. Lutong Town (4.4708333ºN, 114.0038889ºE). From beach forest, within a patch of *Casuarina* with blackwater pools. 25 October 2007. I. Das. USDZ 1.12153. Verified by Kelvin K. P. Lim. First record for Sarawak. Bornean records from Sinkawang, Kalimantan (Indonesia) by Inger (1966. Fieldiana Zool. 52:1–402), Sabah East Malaysia, without locality (Inger and Tan 1996. Raffles Bull. Zool. 44:551–574), Crocker Range, Sabah (Das 2006. Amphibian and Reptile Conservation 4[1]:3–11), and Bandar Seri Begawan, in Brunei Darussalam (Charles 2008. Herpetol. Rev. 39:462–463). Sarawak locality is ca. 115 km W of Brunei record, and choruses of breeding males heard during late afternoons and nights of 25–26 October 2007 indicate species is established locally. Considered introduced by anthropogenic activities in Borneo and is currently spreading west along north coast, and widespread in Southeast Asian mainland (Inger 1999. *In* W. E. Duellman [ed.], Patterns of Distribution of Amphibians: A Global Perspective, pp. 445–482. The John Hopkins University Press, Baltimore and London).

I thank Lee Nyanti, Andrew Alek Tuen, and Matteo Veronesi for supporting field work in Lutong under Project Kuala for Shell Sarawak Berhad and Environmental Resources Management Sdn. Bhd.

Submitted by **INDRANEIL DAS**, Institute of Biodiversity and Environmental Conservation, Universiti Malaysia Sarawak, 94300 Kota Samarahan, Sarawak, Malaysia; e-mail: idas@ibec.unimas.my.

LITHOBATES GRYLIO (Pig Frog). USA: TEXAS: Chambers Co.: Highway 124, 5 km N of High Island (29.61379ºN, 94.38073ºW; WGS 84). 25 June 2008. Collected by Paul Crump. Verified by Carl J. Franklin. University of Texas Arlington (UTADC 3691–3698), and tissue deposited at the MRJ Forstner Frozen Tissue Collection at Texas State University (MF 27033).

Submitted by **PAUL CRUMP** (e-mail: pcrump@houstonzoo.org), **RACHEL ROMMEL**, Department of Conservation and Science, Houston Zoo, 1513 North Macgregor Way, Houston, Texas 77030, USA (e-mail: rrommel@houstonzoo.org); and **JAIME GONZALEZ**, Katy Prairie Conservancy, Katy Prairie Conservancy, Waller, Texas 77098, USA (e-mail: jaimegonzalez72@gmail.com).

LITHOBATES PALUSTRIS (Pickerel Frog). USA: ARKANSAS: Searcy co.: Off AR 14, ca. 2.2 km down Ramblewood Trail in small drainage creek (UTM 15N 0536006E, 3990296N; WGS 84). 26 March 2009. M. B. Connior. Verified by S. E. Trauth. Arkansas State University Museum of Zoology Herpetology Collection (ASUMZ 31312). Adult female caught by hand. First county record filling a distributional gap among surrounding Stone, Marion, and Newton counties (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univeristy of Arkansas Press, Fayetteville. 421 pp.).

Submitted by **MATTHEW B. CONNIOR,** Department of Biological Sciences, Arkansas State University, P.O. Box 599, State University, Arkansas 72467, USA; e-mail: matthew.connior@smail.astate.edu.

LITHOBATES SYLVATICUS (Wood Frog). USA: TENNESSEE: Van Buren Co.: Flooded pit near Piney Falls at Fall Creek Falls State Park (35.67278ºN, 85.375ºW: datum NAD27). 06 January 2009. Matthew L. Brown and Thomas P. Solomon. Verified by A. Floyd Scott. Twenty-two adults and egg masses located, two adults photographed and catalogued at Austin Peay State University Center for Field Biology (APSU 18954).. First county record (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp. Internet version [http://www.apsu.edu/amatlas] contains links to information regarding Tennessee distribution of amphibians recorded since 1996; accessed 17 January 2009). Extends range from nearest documented occurrence by approximately 25 km west.

Submitted by **MATTHEW L. BROWN**, Fall Creek Falls State Park, Pikeville, Tennessee, 37367, USA; e-mail: matthew.brown@state.tn.us

PHYSALAEMUS KROYERI (Kroyer's Dwarf Frog). BRAZIL: PIAUÍ: Municipalidade de Piracuruca: Parque Nacional de Sete Cidades (03.978ºS, 41.556ºW; datum SAD69; 110 m elev.). April 2007. B. B. Annunziata, I. S. Castro, and W. M. Fontenele. February 2009. B. B. Annunziata, M. R. A. Mendes and D. Cisne. Verified by D. Silvano and P. Valdujo. Herpetological Collection of Universidade Estadual do Piauí, Parnaíba (UESPI 0062, 0394–0404). This species ranges from the northern part of the State of Minas Gerais and from the central part of the State of Bahia, north to São José do Bonfim and Mamanguape in State of Paraíba, occurring up to 240 m elev. (Frost 2009 Amphibian Species of the World http://research.amnh.org/herpetology/amphibia/index.php IUCN 2009 Global Amphibian Assessment). First state record, extends distribution ca. 588 SE from the city of São José do Bonfim, Paraíba state (Arzabe et al. 1998 Herpetol. J. 8:111–113), and a new elevation range of the species, up to 110 m.

Submitted by **BRUNO B. ANNUNZIATA**, Departamento de Zoologia, Coleção Herpetológica, Universidade de Brasília (UnB), CEP 70.855-160, Brasília, Distrito Federal, Brazil; **IRISMAR S. CASTRO**, Departamento de Biologia, Universidade Estadual do Piauí (UESPI), CEP 64.202-220, Parnaíba, Piauí, Brazil; **WOLNEY M. SAKTHIVEL**, Kerala Forest Research Institute, Peechi 680 653, Kerala, India.

SPHAENORHYNCHUS PRASINUS**:** BRAZIL: PERNAMBUCO: Municipality of São Lourenço da Mata: Estação Ecológica do Tapacurá (08.03333ºS, 35.18333ºW, WGS 84, elev. 140 m). 10 January 2000. E. Maranhão dos Santos. Coleção Herpetologica da Universidade Federal Rural de Pernambuco, Unidade Acadêmica de Serra Talhada, Serra Talhada, Pernambuco, Brazil (CHUFRPE 966, adult specimen SVL 26.8 mm). Verified by M. Trefault Rodrigues. Previously known from states of Bahia (Centro de Pesquisa

do Cacau, Ilheus municipality (type locality); Teixeira de Freitas municipality, and Mata de São João municipality), and Minas Gerais (Parque Estadual do Rio Doce), Brazil (Bokermann 1973. Brasil. Biol. 33[4ª]:589–594; Silvano and Pimenta 2003. CD-ROM, Ilhéus, IESB/CI/CABS/UFMG/UNICAMP; Juncá 2006. Biota Neotropica May/Aug 2006 6[2], http://www.biotaneotropica.org.br 2006; Feio et al. 1999. Herpetol. Rev. 30:56–57). First state record, extends the known distribution 860 km NE from type locality and 600 km NE from Mata de São João municipality.

Submitted by **EDNILZA MARANHÃO DOS SANTOS**, Unidade Acadêmica de Serra Talhada, Universidade Federal Rural de Pernambuco, 56900-000, Serra Talhada, PE, Brazil; and **GERALDO JORGE BARBOSA DE MOURA**, Post-graduate Program in Biological Sciences, Universidade Federal da Paraíba, 58059-900, Cidade Universitária, João Pessoa, PB, Brazil.

TRACHYCEPHALUS NIGROMACULATUS (Black-spotted Casque-headed Treefrog). BRAZIL: BAHIA: Municipality of Potiraguá: Cedro Farm (0414551ºS, 8265887ºW), 188 m elev. 20 January 2008. M. A. Freitas, T. O. Lima, and T. F. Miranda. Museu de Zoologia da Universidade Federal da Bahia, Salvador, Brazil (MZUFBA 7825, collected at night below terrestrial bromeliads). Verified by I. Nunes. Previously known from coastal regions of southern Brazil. First state record extends distribution ca. 380 km N from Fundão Municipality, Espírito Santo State (Ramos and Gasparini 2004. Anfíbios do Goiapaba-Açu, Fundão, estado do Espírito Santo. Fundão. 75 pp.).

Submitted by **MARCO ANTÔNIO DE FREITAS,** Programa de pós-graduação em zoologia, UESC (Universidade Estadual de Santa Cruz), CEP 46.500-000 Rodovia Ilhéus/Itabuna, Ilhéus, Bahia, Brazil **(**e-mail: philodryas@hotmail.com); and **TIAGO DE OLIVEIRA LIMA,** Rua São Joaquim n 11, Sagrada Família, CEP 31-700-000, Belo Horizonte, Minas Gerais, Brazil (e- mail: tiagoboidae@yahoo.com.br).

TESTUDINES – TURTLES

TERRAPENE CAROLINA CAROLINA (Eastern Box Turtle). USA: OHIO: Summit Co.: Bath Township, corner of Kemery and Glengary Roads (41.18437ºN, 81.60213ºW). 10 July 2006. Scott and Alice Mason. Verified by Jeffrey G. Davis. Cincinnati Museum Center (CMC Herpetology Photodocumentation Collection HP 245–247). New county record (Wynn and Moody 2006. Ohio Turtle, Lizard, and Snake Atlas. Ohio Biological Survey Misc. Contrib. No. 10, Columbus).

Submitted by **JOHN W. FERNER**, Department of Biology, Thomas More College, Crestview Hills, Kentucky 41017, USA (e–mail: john.ferner@thomasmore.edu); and **VERNA VANDER KOOI**, 1903 Glengary Rd., Akron, Ohio 44333, USA.

TRACHEMYS SCRIPTA ELEGANS (Red-eared Slider) USA: TEXAS: Eastland Co.: 1.7 miles S of Cisco on TX 183, (32.35350˚N, 98.96579˚W; datum WGS84). 05 April 2009. Collected by D. J. Leavitt. Verified by T. J. Hibbitts. Texas Cooperative Wildlife Collection (TCWC 93636). One individual found dead on the road. New county record fills gap within adjacent counties (Dixon 2000. Reptiles and Amphibians of Texas. Texas A&M Univ. Press, College Station. 500 pp.).

Submitted by **DANIEL J. LEAVITT,** Texas Cooperative Wildlife Collection, Department of Wildlife and Fisheries Sciences, Texas A&M University, College Station, Texas 77843, USA.

TRACHEMYS SCRIPTA SCRIPTA (Yellow-bellied Slider) × ***T. S. ELEGANS*** (Red-eared Slider). USA: VIRGINIA: Chesterfield Co.: City of Petersburg (Virginia State University, Randolph Farm), 4415 River Road (3722881°N, 77.43800°W; WGS84). 22 September 2008. Christian A. d'Orgeix and Edward N. Sismour. Verified by Jeffrey C. Beane. North Carolina State Museum (NCSM 74672–74675). Intergrades between native *T. s. scripta* and introduced *T. s. elegans* occur in southeastern Virginia (Mitchell 1994. The Reptiles of Virginia. Smithsonian Institution Press, Washingon, DC. 352 pp.). This new county record is ca. 75 km NW from the nearest known intergrade population in James City Co., Virginia (Mitchell 1994, *op. cit.*). An adult female, adult male, and two juveniles were caught in floating (1.2 m L × 1.2 m W × 1.2 m H), 0.6 cm^2 mesh, black polyethylene fish aquaculture cages in two 0.1 ha artificial aquaculture ponds located ca. 430 m N of the Appomattox River. These individuals represent a range of markings on the head and plastron (i.e., amount and pattern of red and yellow pigment on the head and black spots on the plastron) between the two parental species. Backcrossing of intergrades with parental subspecies or among themselves would explain the range of observed phenotypic variation in the intergrades. We hypothesize that original colonization of these ponds occurred through immigration of the parental subspecies and possibly intergrades from the Appomattox River.

Field work supported through S. Newton (Evans-Allen program, USDA/CSREES, P. L. 95-113, Sec. 1445) and through Virginia General Assembly appropriations for the Virginia State University Agricultural Research Station.

Submitted by **CHRISTIAN A. D'ORGEIX,** National Evolutionary Synthesis Center, 2024 West Main Street, Durham, North Carolina 27701, USA; Department of Biology, Virginia State University, Petersburg, Virginia 23806, USA (e-mail: cdorgeix@vsu.edu); and **EDWARD N. SISMOUR,** Agricultural Research Station, School of Agriculture, Virginia State University, Petersburg, Virginia 23806, USA (e-mail: esismour@vsu.edu).

SQUAMATA – LIZARDS

ANOLIS CHLOROCYANUS (Hispaniolan Green Anole). USA: FLORIDA: Palm Beach Co.: 1301 Summit Boulevard, West Palm Beach, The Palm Beach Zoo (26.667731°N, 80.068944°W, WGS84; elev. < 1m). 16 February 2009. Brian J. Camposano and Mark D. Halvorsen. Verified by Joseph Burgess. Florida Museum of Natural History (UF 154683–84). New county record and extends the range ca. 42 km NE of the closest known locality in Parkland, Broward Co. (Butterfield et al. 1994. Herpetol. Rev. 25:77–78).

Submitted by **BRIAN J. CAMPOSANO**, Division of Herpetology, Florida Museum of Natural History, Dickinson Hall, University of Florida, Gainesville, Florida 32611, USA (e-mail: biscuit1@ufl.edu); **MARK D. HALVORSEN,** Curator of Herpetology, The Palm Beach Zoo, 1301 Summit Boulevard, West Palm Beach, Florida 33405, USA (e-mail: mhalvorsen@palmbeachzoo.

org); and **KENNETH L. KRYSKO**, Division of Herpetology, Florida Museum of Natural History, Dickinson Hall, University of Florida, Gainesville, Florida 32611, USA (e-mail: kenneyk@flmnh.ufl.edu).

ANOLIS DISTICHUS (Bark Anole). USA: FLORIDA: COLLIER CO.: 722 16th Avenue South, Naples (26.12797°N, 81.79576°W; WGS84; elev. < 1 m). 12 April 2008. Steve A. Johnson and Sam Logue. Verified by Kenneth L. Krysko. Florida Museum of Natural History (UF 152789). New county record and extends the range ca. 150 km NW of the closest known locality at SR 997 & SW 300 Street, Homestead, Miami-Dade Co. (UF 147676, Meshaka et al. 2004. The Exotic Amphibians and Reptiles of Florida. Krieger Publ. Co., Malabar, Florida. 155 pp.).

PHELSUMA MADAGASCARIENSIS (Madagascar Day Gecko). USA: FLORIDA: MONROE CO.: Sugarloaf Key, 19580 Mayan Street (24.6682797ºN, 81.5277097ºW; WGS84; elev. < 1 m). 31 March 2009. Andrew P. Borgia. Verified by Kevin M. Enge. Florida Museum of Natural History (Photographic voucher UF 155282). First voucher specimen and seventh known island in the Florida Keys to which this species has been introduced (Krysko and Sheehy 2005. Caribbean J. Sci. 41:169–172, Krysko and Hooper 2007. Gekko 5:33–38).

Submitted by **KENNETH L. KRYSKO**, Division of Herpetology, Florida Museum of Natural History, Dickinson Hall, University of Florida, Gainesville, Florida 32611, USA (e-mail: kenneyk@flmnh.ufl.edu); and **ANDREW P. BORGIA**, P.O. Box 4346, Key West, Florida 33041, USA.

PSEUDOCALOTES MICROLEPIS (Small-scaled Montane Forest Lizard). THAILAND: CHIANG RAI PROVINCE: Wieng Pa Pao District, Tambon (= Subdistrict) Pagnew, Moo. 7.6 km S of Ban Pa Miang Mae Hang (19.3505556ºN, 99.5341667ºE). 18 November 2007. K. Kunya. Korat Zoo Museum (KZM 002) and Queen Saovabha Memorial Institute, Bangkok (QSMI 1001). Verified by M. Sumontha (Ranong Marine Fisheries Station). First provincial record based on the rejection by Pauwels et al. (2003. Nat. Hist. J. Chulalongkorn Univ. 3[1]:23–53) of a record from Phetchaburi Province in west Thailand. Species known in Thailand from northern provinces of Chiang Mai and Chiang Rai and northeastern provinces of Chaiyaphum and Loei (Nabhitabhata et al. "2000" 2004. Checklist of Amphibians and Reptiles in Thailand. Office of Environmental Policy and Planning, Bangkok. 152 pp.). We thank L. Chanhome (QSMI) for providing working facilities.

Submitted by **OLIVIER S. G. PAUWELS**, Département des Vertébrés Récents, Institut Royal des Sciences naturelles de Belgique, Rue Vautier 29, 1000 Brussels, Belgium (e-mail: osgpauwels@yahoo.fr); and **KIRATI KUNYA**, Korat Zoo, Muang District, Nakhon Ratchasima, Thailand (e-mail: kkunya2006@yahoo.com).

SQUAMATA – SNAKES

BOA CONSTRICTOR (Boa Constrictor). MÉXICO: HIDALGO. Municipality of Huehuetla, Barrio Aztlán (98.0836°N, 20.43125°W; WSG 84), 496 m elev. 28 August 2008. Froylán Ramírez, Alejandro Ramírez, Adriana López, Nallely Morales, Arely Penguilly, and Arely Flores. Verified by Norma Manríquez-Morán. Colección Herpetológica, Centro de Investigaciones Biológicas, Universidad Autónoma del Estado de Hidalgo (CIB-UAEH 1623). First record for the municipality, extending the range in Hidalgo ca. 99 km S from Tepehuacán de Guerrero (Mendoza et al. 2006. *In* A. Ramírez-Bautista et al. [eds.], Inventarios Herpetofaunísticos de México: Avances en el Conocimiento de su Biodiversidad, pp. 99–109. Publ. Soc. Herpetol. Mex. No. 3. México, D.F.). The snake was found in tropical deciduous forest. Fieldwork was funded by CONACyT- 43761.

Submitted by **IRENE GOYENECHEA** (e-mail: ireneg@uaeh.edu.mx), **JESÚS M. CASTILLO, FROYLÁN RAMÍREZ-RESÉNDIZ,** and **ALEJANDRO RAMÍREZ-PÉREZ**, Centro de Investigaciones Biológicas (CIB), Universidad Autónoma del Estado de Hidalgo, A.P. 1-69 Plaza Juárez, Pachuca, Hidalgo, México.

BUNGARUS SLOWINSKII (Red River Krait). VIETNAM: QUANG NAM PROVINCE: Tay Giang District: B Ha Lee Commune (16.0086111ºN, 107.521666ºE), 750 m elev. 27 April 2006. Doan Van Kien. IEBR 2978. Verified by David Kizirian. Adult male. Previously known from Lao Cai and Yen Bai provinces (Kuch et al. 2005. Copeia 2005:818–833). Third and southernmost record from Vietnam, and ca. 750 km from type locality in Yen Bai Province.

Submitted by **DOAN VAN KIEN** (e-mail: doanvankien@yahoo.fr) and **NGUYEN QUANG TRUONG** (e-mail: NQT2@YAHOO.COM), Institute of Ecology and Biological Resources, 18 Hoang Quoc Viet, Hanoi, Vietnam.

COLUBER (= MASTICOPHIS) FLAGELLUM FLAGELLUM (Eastern Coachwhip). USA: GEORGIA: CHARLTON CO.: ~16 km SSW of St. George (straight distance from town center) (30.39450°N, 82.11297°W; WGS84). 16 June 2004. Nathan H. Nazdrowicz. Verified by John Jensen. Georgia Museum of Natural History photographic voucher (GMNH 50108). Photographed and released. New county record (Jensen et al. [eds.] 2008. Amphibians and Reptiles of Georgia. Univ. Georgia Press, Athens, 575 pp.).

Submitted by **NATHAN H. NAZDROWICZ**, Department of Entomology and Wildlife Ecology, University of Delaware, Newark, Delaware 19716, USA; e-mail: spinifer@aol.com.

COLUBER* (= *MASTICOPHIS*) *FLAGELLUM (Coachwhip). USA: GEORGIA: EMANUEL CO.: Ohoopee Dunes Natural Area, Hall's Bridge Tract, just south of Hall's Bridge Rd., 2.33 km NW of intersection with Frank Wimberly Rd. (32.530277°N, 82.4516861°W; WGS 84). 13 December 2007. Kerry T. Nelson and Andrew M. Durso. Verified by Kenneth L. Krysko. FLMNH 154856. New county record (Jensen et al. [eds.] 2008. Amphibians and Reptiles of Georgia. Univ. Georgia Press, Athens, 575 pp.). A juvenile *M. flagellum* was found on a sandhill under a log at ca. 1230 h. This record is ca. 27.6 km NW of a 2008 record from

Candler Co., Georgia (FLMNH 154400), and ca. 32 km S of a 1994 record from Jefferson Co., Georgia (SSM 13101).

Submitted by **KERRY T. NELSON**, University of Georgia, Warnell School of Forestry and Natural Resources, Athens, Georgia 30602, USA (e-mail: kerrytnelson@gmail.com); and **ANDREW M. DURSO**, University of Georgia, Odum School of Ecology, Athens, Georgia 30602, USA (e-mail: amdurso@gmail.com).

FARANCIA ERYTROGRAMMA ERYTROGRAMMA (Common Rainbow Snake). USA: GEORGIA: Charlton Co.: west bank of St. Marys River at Earnest A. Bell Bridge, Moniac Rd. (Hwy 94) near St. George (30.52438°N, 82.01898°W; WGS84). 31 March 2006. Nathan H. Nazdrowicz and Nigel Watson. Verified by John Jensen. Georgia Museum of Natural History photographic voucher (GMNH 50107). Found under rock on steep bank of river. New county record (Jensen et al. [eds.] 2008. Amphibians and Reptiles of Georgia. Univ. Georgia Press, Athens, 575 pp.).

Submitted by **NATHAN H. NAZDROWICZ** (e-mail: spinifer@aol.com) and **NIGEL WATSON** (e-mail: nigelgwatson@yahoo.com), Department of Entomology and Wildlife Ecology, University of Delaware, Newark, Delaware 19716, USA.

HYDRODYNASTES GIGAS (False Water Cobra). BRAZIL: PIAUÍ: Municipality of Ilha Grande: 2.8219°S, 41.8245°W; datum WGS84, 4 m elev. 23 December 2008. Pedro da Costa Silva. Instituto Butantan, São Paulo (IBSP 77245). Verified by V. J. Germano. Species widely distributed in South America with recognized records from Suriname, French Guyana, Venezuela, Peru, Bolivia, Paraguay, Argentina, and Brazil (Giraudo and Scrocchi. 2002. Smithson. Herpetol. Inf. Serv. 132:1–53). In Brazil, the species has been recorded mainly in the northern, southeastern, and central western states (Franco et al. 2007. Zootaxa. 1613:57–65), however, there is a unique record for northeastern Brazil in Paraíba State (Pereira Filho and Montingelli. 2006. Herpetol. Rev. 37:497). This is the first record for the state of Piauí, extending the distribution previously known as follow: ca. 900 km NW from the municipality of João Pessoa, Paraíba, Brazil (Pereira Filho and Montingelli, *op. cit.*); ca. 1000 km NE from the municipality of Mateiros, Tocantins, Brazil (Vitt et al. 2005. Occas. Pap. Sam Noble Oklahoma Mus. Nat. Hist. [2]:1–24); and ca. 340 km E from the municipality of Perim-Mirim, Maranhão, Brazil (Franco et al. 2007, *op. cit.*).

Submitted by **ROBERTA ROCHA SILVA-LEITE**, Universidade Federal do Piauí, Campus Ministro Reis Velloso, Av. São Sebastião nº 2819, Parnaíba, Piauí, Brazil, CEP 64202-020 (e-mail: roberta.ufpi@gmail.com); **DANIEL LOEBMANN**, Departamento de Zoologia, Instituto de Biociências, Universidade Estadual Paulista, Rio Claro, São Paulo, Brazil, Caixa Postal 199, CEP 13506-970; **PEDRO DA COSTA SILVA**, Associação de Guias e Condutores de Turismo de Ilha Grande, Centro, Ilha Grande, Piauí, Brazil, CEP 64224-970.

LAMPROPELTIS TRIANGULUM (Milksnake). USA: TEXAS: Nacogdoches Co.: Stephen F. Austin Experimental Forest (31.49726°N, 094.78005°W; WGS 84). Stephen F. Austin State University Vertebrate Collection 4916. 01 April 2008 by T. B. Cotten. Verified by T. J. Hibbitts. New county record (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M Univ. Press, College Station. 129 pp.).

Submitted by **TAYLOR B. COTTEN**, Department of Biology, Stephen F. Austin State University, P.O. Box 13003, S.F.A. Station, Nacogdoches, Texas 75962-3003, USA.

MICRURUS FULVIUS (Harlequin Coralsnake). USA: ALABAMA: Coosa Co.: Cahaba and Columbiana Forever Wild Tract, Coosa Wildlife Management Area (32.8°N, 86.4°W; WGS84). 20 April 2009. Nicholas W. Sharp and Josh D. Landrum. Verified by Robert Mount. Alabama Herpetological Atlas Project AHAP-D-203. Photographed and released. Previously believed to be extirpated in the county. Although range maps typically depict a disjunct population in the Alabama Piedmont north of the Fall Line (Mount 1975. Reptiles and Amphibians of Alabama. Agricultural Experiment Station, Auburn University. 347 pp.), this is the only record of such in 40 years. Auburn University holds only one specimen from Coosa Co., lacking a date and locality; collected sometime before 1975 near Strickland Crossroads, ca. 13 miles N of the current specimen (R. Mount, pers. comm.). Adult captured traversing open ground at 1040 h after heavy rains the previous evening. Habitat was mature Longleaf Pine over well-drained, sandy loam ridges and steep slopes.

Submitted by **NICHOLAS W. SHARP**, Alabama Department of Conservation and Natural Resources, State Lands Division, 64 North Union Street, Montgomery, Alabama 36104, USA; e-mail: nicholas.w.sharp@gmail.com.

MICRURUS FULVIUS (Harlequin Coralsnake). USA: GEORGIA: Talbot Co.: Manchester, ca. 10.8 km E (32.865223ºN, 84.493107ºW; NAD83), 252 m elev. 13 October 2008. Nathan A. Klaus. UF 153883. Verified by Kenneth Krysko. First county record and only the fifth documented specimen from the Pine Mountain/Piedmont physiographic region (Stevenson and Moulis 2008. *In* Jensen et al. [eds.], Amphibians and Reptiles of Georgia, pp. 421–423. Univ. Georgia Press, Athens. 575 pp.). Not seen in this area since 1977 (Pike Co. specimen, AUM 32733). Found on surface along a ridgetop in an area of old growth montane Longleaf Pine (*Pinus palustris*) and Chestnut Oak (*Quercus montana*) forest with rocky/gravelly soil.

Submitted by **NATHAN A. KLAUS** (e-mail: nathan.klaus@gadnr.org), and **JOHN B. JENSEN**, Georgia Department of Natural Resources, Nongame Conservation Section, 116 Rum Creek Drive, Forsyth, Georgia 31029, USA.

MICRURUS FULVIUS (Harlequin Coralsnake). USA: GEORGIA: Telfair Co.: Horse River Wildlife Management Area (31.83007°N, 82.85688°W; WGS84). 29 March 2008. Nigel Watson and Nathan H. Nazdrowicz. Verified by John Jensen. Georgia Museum of Natural History photographic voucher (GMNH 50106). One adult observed crossing a dirt road at night. New county record (Jensen et al. [eds.] 2008. Amphibians and Reptiles of Georgia. Univ. Georgia Press, Athens, 575 pp.).

Submitted by **NATHAN H. NAZDROWICZ** (e-mail: spinifer@aol.com) and **NIGEL WATSON** (e-mail: nigelgwatson@yahoo.com), Department of Entomology and Wildlife Ecology, University of Delaware, Newark, Delaware 19716, USA.

MICRURUS LEMNISCATUS LEMNISCATUS (Guiana's Ribbon Coralsnake). BRAZIL: CEARÁ: MUNICIPALITY OF UBAJARA: Ubajara National Park (03.830417°S, 40.900278°W; datum WGS84), 445 m elev. 13 November 2008. D. Loebmann. Verified by F. L. Franco. Coleção Instituto Butantan, São Paulo, Brazil (IBSP 77079). Species recorded for the Amazon Rainforest Biome with distribution in Guyana, Suriname, French Guyana, Colombia, Bolivia, Ecuador, Peru, Venezuela, and Brazilian states of Acre, Amapá, Amazonas, Pará, Maranhão, Rondônia, and Roraima (Cunha and Nascimento 1993. Bol. Mus. Para. Emílio Goeldi, sér. Zool. 9[1]:1–191; Roze 1996. Coral Snakes of the Americas: Biology, Identification, and Venoms. Krieger Publishing Company, Malabar, Florida. 328 pp.; Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Cornell University Press, Ithaca, New York. 1032 pp.; Feitosa 2006. Unpubl. thesis. Universidade Federal do Pará, Belém, Pará. 170 pp.). First record for Ceará state and the Caatinga biome, extending distribution ca. 350 km E from state of Maranhão, in surroundings of municipality of Coroatá, Brazil (Campbell and Lamar 2004, *op. cit.*).

Submitted by **DANIEL LOEBMANN**, Departamento de Zoologia, Instituto de Biociências, Universidade Estadual Paulista, Rio Claro, São Paulo, Brazil, Caixa Postal 199, CEP 13506-970; e-mail: contato@danielloebmann.com.

OXYRHOPUS MELANOGENYS ORIENTALIS (Black-headed Calico Snake). BRAZIL: CEARÁ: MUNICIPALITY OF UBAJARA: 3.8450°S, 40.9344°W (datum WGS84), 857 m elev. 10 February 2008. D. Loebmann. Coleção Instituto Butantan, São Paulo, Brazil (IBSP 77061); MUNICIPALITY OF GUARAMIRANGA: 04.2723°S, 38.9492°W, 844 m elev. 10 December 2006. T. Pinto, C. Albano, and I. J. Roberto (IBSP 76979); MUNICIPALITY OF PACOTI: 04.2208°S, 38.9259°W, 758 m elev. 15 April 2006. C. Albano and I. J. Roberto. (IBSP 77980). All verified by F. L. Franco. Subspecies distributed in the Brazilian states of Pará and Maranhão (Cunha and Nascimento 1993. Bol. Mus. Para. Emílio Goeldi, sér. Zool. 9[1]:1–191). First state records represented by two isolated populations in the relict rain forests of the plateau of Ibiapaba and Baturité Hills. Also the first records in the Caatinga biome, extending distribution ca. 480 km E (Plateau of Ibiapaba) and ca. 710 km E (Baturité Hills) from municipality of Santa Inês, state of Maranhão, Brazil (Cunha and Nascimento 1983. Bol. Mus. Para. Emílio Goeldi, sér. Zool. [122]:1–42).

PANTHEROPHIS GUTTATUS (Red Cornsnake). USA: GEORGIA: EMANUEL CO.: DOR adult male on Hall's Bridge Rd. (CR 160), ~10.75 km SW of Swainsboro (straight distance from town center) (32.54500°N, 82.43683°W; WGS84). 02 April 2002. Nathan H. Nazdrowicz and Shawn T. Dash. Verified by Elizabeth McGhee. Georgia Museum of Natural History (GMNH 50109). New county record (Jensen et al. [eds.] 2008. Amphibians and Reptiles of Georgia. Univ. Georgia Press, Athens, 575 pp.).

Submitted by **NATHAN H. NAZDROWICZ,** Department of Entomology and Wildlife Ecology, University of Delaware, Newark, Delaware 19716, USA; e-mail: spinifer@aol.com.

RAMPHOTYPHLOPS BRAMINUS (Brahminy Blindsnake). USA: TEXAS: HIDALGO CO.: McAllen (26.261983°N, 98.210933W; WGS 84). 15 March 2009. John Merino. Verified by Frank W. Judd. University of Texas – Pan American Vertebrate Museum (UTPA) 03092. Female (11.3 cm total length and 0.5879 g) found under flat landscaping stones alongside ant colonies in a residential area. This is the first county record and third known locality in the state. Previously reported in adjacent Cameron Co. (Dixon 2000. Amphibians and Reptiles of Texas. 2nd ed. Univ. of Texas A&M Press, College Station. viii + 421 pp.; Godwin et al. 2007. Herpetol. Rev. 38:356; Wallach. 2008. Bull. Chicago Herpetol. Soc. 43[5]:80–82.). Our record lies ca. 88 km WNW of the nearest (= Cameron Co.) published record. On the same day, another was captured at a residence in Edinburg, also in Hidalgo Co. (26.287050°N, 98.175717°W; WGS 84). This individual was found underneath an established plant in a flowerbed. On 19 March 2009 a third individual was captured by G. Martinez and J. M. Cantu in Brownsville, Cameron Co. in a different locality (University of Texas – Brownsville campus) from the previous Cameron Co. record. From 20–30 March 2009 an additional 13 specimens were captured at the two Hidalgo Co. locations. After its first mention in the area over 20 years ago, it appears that *R. braminus* is now well established in the Lower Rio Grande Valley.

Submitted by **JOHN MERINO**, Department of Biology, University of Texas – Pan American, Edinburg, Texas 78539, USA; **LEE BAINES**, Department of Biology, South Texas College, 3201 W. Pecan Blvd., McAllen, Texas 78501, USA; and **FREDERIC ZAIDAN III,** Department of Biology, University of Texas – Pan American, Edinburg, Texas 78539, USA (e-mail: fzaidan@utpa.edu).

SCOLECOPHIS ATROCINCTUS (Black-Banded Snake). HONDURAS: CORTÉS: Sierra de Omoa, Parque Nacional El Cusuco, Buenos Aires Village (15.499722ºN, 88.176667ºW; WGS84), 1120 m elev. 27 July 2007. Jonathan E. Kolby and Douglas Fraser. Verified by Larry D. Wilson. (USNM Herp Images 2685–2688). First record for Cortés, extending the range ca. 111 km N of Lempira, Gracias (FMNH 28559). It is also a 420 m upward extension in elevation from the highest previous record of 700 m reported by Kohler (2003. Reptiles of Central America. Herpeton Verlag Elke Kohler. 367 pp.). The snake was found DOR in a deforested region converted to coffee cultivation.

Submitted by **JONATHAN E. KOLBY**, The Conservation Agency, 6 Swinburne Street, Jamestown, Rhode Island 02835, USA (e-mail: J_Kolby@hotmail.com); and **DOUGLAS FRASER**, Operation Wallacea, Wallace House, Old Bolingbroke, Lincolnshire PE23 4EX, United Kingdom.

SIBON NEBULATUS (Cloudy Snail-eating Snake). MÉXICO: JALISCO: MUNICIPALITY OF SAN SEBASTIÁN DEL OESTE: on the road from Mascota to Ixtapa (20.78017°N, 104.92650°W; WGS84), 917 m elev. 14 June 2007. U. O. García-Vázquez and R. C. Jadin. Both verified by E. N. Smith. Museo de Zoología, Facultad de Ciencias UNAM (MZFC 22051). First verified municipality record that

bridges a distribution gap between Tepic, Nayarit (80 km N) and Chamela, Jalisco (140 km S) (Zweifel 1959. Amer. Mus. Novit. 1953:1–13; Ramirez-Bautista 1994. Manual y Claves Ilustradas de los Anfibios y Reptiles de la Región de Chamela, Jalisco. UNAM, Cuadernos del Inst. de Biol. 23:1–127). Another individual was found nearby on the same road and date (20.81104°N, 104.95510°W, 710 m elev.; UTA R-55780). The vegetation at the capture site was a patch of pristine tropical deciduous forest, although much of what remained was in the process of being burned for agriculture and other developmental purposes.

Submitted by **ROBERT C. JADIN,** Amphibian and Reptile Diversity Research Center and Department of Biology, University of Texas at Arlington, Arlington, Texas 76019, USA (e-mail: snakeman1982@hotmail.com); and **URI OMAR GARCÍA-VÁZQUEZ,** Museo de Zoología, Facultad de Ciencias, Universidad Nacional Autónoma de México, A.P. 70-399, México D.F. (e-mail: urigarcia@gmail.com).

SPILOTES PULLATUS (Tropical Rat Snake). MÉXICO: HIDALGO: Municipality of Huehuetla: El Paraíso (98.13972°N, 20.43125°W, WGS 84), 498 m elev. 28 August 2008. Adán Martínez Sosa. Verified by Norma Manríquez-Morán. Colección Herpetológica, Centro de Investigaciones Biológicas, Universidad Autónoma del Estado de Hidalgo (CIB-UAEH 1622). First municipality record, extending the range in Hidalgo ca. 92 km S from 2.3 km E of San Felipe Orizatlán, Orizatlán (Mendoza-Quijano and Hernández 2001. Herpetol. Rev. 32:279). The snake was found in a coffee field surrounded by tropical deciduous forest. Fieldwork was funded by CONACyT- 43761.

Submitted by **IRENE GOYENECHEA** (e-mail: ireneg@uaeh.edu.mx), **JESÚS M. CASTILLO, FROYLÁN RAMÍREZ-RESÉNDIZ,** and **ALEJANDRO RAMÍREZ-PÉREZ**, Centro de Investigaciones Biológicas (CIB), Universidad Autónoma del Estado de Hidalgo, A.P. 1-69 Plaza Juárez, Pachuca, Hidalgo, México.

STORERIA DEKAYI TEXANA (Texas Brownsnake). USA: TEXAS: Stephens Co.: S of State Highway 180 and E of Ranch Road 717 near Caddo (32.64668ºN, 98.61677ºW). 05 April 2008. Collected by J. W. Streicher. Verified by Carl J. Franklin. Deposited in the herpetological collection of the University of Texas at Arlington (UTA R-56675, field ID: JWS 053). Adult (SVL = 225 mm, TL = 33 mm) found under a roadside log represents first county record. This account is a local range extension W (ca. 4 km) and fills in a longitudinal gap (ca. 50 km) within the known distribution of *S. d. texana* (Dixon 2000. Amphibians and Reptiles of Texas, 2nd ed. Texas A&M University Press, College Station. 421 pp.; Werler and Dixon 2000. Texas Snakes. University of Texas Press, Austin. 437 pp.). Collected under Texas Parks and Wildlife scientific permit number SPR-0707-1387.

Submitted by **JEFFREY W. STREICHER**, Amphibian and Reptile Diversity Research Center, Department of Biology, The University of Texas at Arlington, Arlington, Texas 76019, USA; e-mail: streicher@uta.edu.

STORERIA DEKAYI WRIGHTORUM (Midland Brownsnake). USA: ARKANSAS: Lincoln Co.: 1.6 km E Palmyra (33.552712°N, 91.563533°W; NAD83). 05 May 2001. M. B. Gannet. Verified by S. E. Trauth. Arkansas State University Herpetological Museum (ASUMZ 31321). New county record filling a distributional hiatus among Arkansas and Cleveland counties (Trauth et al. 2004. Amphibians and Reptiles of Arkansas. Univ. Arkansas Press, Fayetteville. 421 pp.). Since the publication of Trauth et al. (*op. cit.*), no fewer than seven new county records in various parts of the state have been documented for this snake.

Submitted by **CHRIS T. McALLISTER**, RapidWrite, 102 Brown Street, Hot Springs National Park, Arkansas 71913, USA (e-mail: drctmcallister@aol.com); and **HENRY W. ROBISON**, Department of Biology, Southern Arkansas University, Magnolia, Arkansas 71754, USA (e-mail: hwrobison@suddenlink.net).

VIRGINIA VALERIAE ELEGANS (Western Smooth Earthsnake). USA: ARKANSAS: Howard Co.: 9.7 km NW Center Point off US 278 (34.025766°N, 93.571243°W; NAD83). 10 June 2004. S. Fowler. Verified by S. E. Trauth. Arkansas State University Herpetological Museum (ASUMZ 31322). New county record filling a distributional hiatus in southwestern Arkansas south of previous records in Polk Co. (Trauth et al. 2004. Amphibians and Reptiles of Arkansas. Univ. Arkansas Press, Fayetteville. 421 pp.).

Submitted by **CHRIS T. McALLISTER**, RapidWrite, 102 Brown Street, Hot Springs National Park, Arkansas 71913, USA (e-mail: drctmcallister@aol.com); and **HENRY W. ROBISON**, Department of Biology, Southern Arkansas University, Magnolia, Arkansas 71754, USA (e-mail: hwrobison@suddenlink.net).

and

ROBERT H. MOUNT
Department of Biological Sciences, Auburn University 331 Funchess Hall Auburn, Alabama 36849, USA

The distribution of Alabama's herpetofauna was treated thoroughly in Mount's (1975) regional field guide. Since its publication, few additional distribution contributions for Alabama

(mostly in the form of single-taxon notes) have appeared. Although most counties in Alabama have numerous recorded taxa, a few counties have not been sampled extensively and have fewer than 18 species recorded. To address this situation, we began road cruise surveys on rainy nights in counties with few records. In addition, we have included new records discovered during class field trips and other related activities. Here we report 101 new county records for Alabama. These new records include at least one new county record for 48 species. All new records were verified by Craig Guyer.

Caudata – Salamanders

Ambystoma opacum (Marbled Salamander). DALE CO.: Found AOR 0.3 km W of Judy Creek on Dale County Rd. 36 (31.462594°N, 85.574776°W; WGS 84). 29 December 2007. S. Graham and S. Hoss. AHAP-D 77. LOWNDES CO.: Found AOR on Lowndes County Rd. 40 (32.324877°N, 86.676382°W; WGS 84). 18 October 2007. S. Graham. AHAP-D 64.

Ambystoma talpoideum (Mole Salamander). LOWNDES CO.: Lowndes WMA. Captured by dipnet in shallow marsh (32.357364°N, 86.731320°W; WGS 84). 20 September 2008. S. Graham and K. Gray. AHAP-D 154–155.

Ambystoma tigrinum (Eastern Tiger Salamander). BULLOCK CO.: Collected AOR in Union Springs, crossing US Hwy 29 in historic district at intersection with Hunter St. (32.15068°N, 85.713527°W; WGS 84). 10 December 2008. S. Graham, R. Birkhead, and K. Gray. AHAP-D 176.

Cryptobranchus alleganiensis (Hellbender). LIMESTONE CO.: Caught on fishing line in Sugar Creek at Buck Island Road (State Rt. 99) bridge (34.944524°N, 87.155586°W; WGS 84). 09 March 1990. H. Bloodworth. Photograph of H. Bloodworth and specimen appeared in *Athens News Courier* 25 March 1990; locality and additional information verified by M. Bailey and R. Mount. Newspaper clipping with photo and other information entered into AUM as AHAP-P182. This represents a new county record and one of the most recent verified records for a hellbender in Alabama.

Eurycea cirrigera. (Southern Two-lined Salamander). HALE CO.: Payne Lake Recreational Area, Talladega National Forest. In spring W of Lake. (32.886059°N, 87.445250°W; WGS 84). 20 September 2008. S. Graham and K. Gray. AHAP-D 167.

Eurycea guttolineata (Three-lined Salamander). CRENSHAW CO.: In Threemile Cr. floodplain ~ 25 m E of US Hwy 29 (31.520517°N, 86.335433°W; WGS 84). 18 March 2008. S. Graham. AHAP-D 105. HALE CO.: Payne Lake Recreational Area, Talladega National Forest. In swampy area S. of dam. (32.878206°N, 87.443716°W; WGS 84). 20 September 2008. S. Graham and K. Gray. AHAP-D 157.

Hemidactylium scutatum (Four-toed Salamander). LAMAR CO.: Found AOR Lamar County Rd. 12 .64 km W of Mud Creek Rd. intersection (33.577378°N, 88.144967°W; WGS 84). 29 November 2008. S. Graham and K. Gray. AHAP-D 163. MARENGO CO.: 5.8 km (air km) NE of Dixon's Mill. 1 January 1977. J. Autery. AUM 29664.

Notophthalmus viridescens (Eastern Newt). BULLOCK CO.: Found DOR on Bullock County Road 102 (32.22618°N, 85.4796052°W; WGS 84). 29 December 2007. S. Graham and S. Hoss. AUM 37612. CRENSHAW CO.: Found AOR Crenshaw County Rd. 59 NE of Luverne (31.751883°N, 86.232050°W; WGS 84). 10 December 2008. S. Graham, R. Birkhead, and K. Gray. AHAP-D 168. LAMAR CO.: Found AOR on State Rt. 17 N of Millport 10m N of bridge over Luxapalilla Cr. (33.575406°N, 88.083639°W; WGS 84). 29 November 2008. S. Graham and K. Gray. AHAP-D 162. LOWNDES CO.: Collected AOR on Brownshill Rd. ~ 200m W of Lowndes County Rd. 40 (32.314128°N, 86.584818°W; WGS 84). 21 September 2007. S. Graham, S. Hoss, D. Steen, V. Johnson. AHAP-D 97. WILCOX CO.: Near dam of large beaver marsh along Howard Steen Rd. 3.86 km SW of Wilcox County Rd. 4 (31.884343°N, 86.913055°W; WGS 84). 5 May 2008. S. Graham and R. Birkhead. AHAP-D 99.

Plethodon grobmani (Southeastern Slimy Salamander). CRENSHAW CO.: In Floodplain of Threemile Cr. ~ 25 m E of US Hwy 29 (31.520517°N, 86.335433°W; WGS 84). 18 March 2008. S. Graham. AHAP-D 106. LOWNDES CO.: Collected AOR on Lowndes County Rd. 40 (32.325749°N, 86.731768°W; WGS 84). 18 November 2007. S. Graham and K. Gray. AHAP-D 68. These specimens were not assigned to this taxon using molecular methods; they were assumed to be *P. grobmani* based on existing range maps (Lannoo, 2005) and in any event represent new county records for a species of the *P. glutinosus* complex.

Pseudotriton ruber (Southern Red Salamander). CRENSHAW CO.: In seepage S of Threemile Cr. floodplain ~ 25 m E of US Hwy 29 (31.520517°N, 86.335433°W; WGS 84). 18 March 2008. S. Graham. AHAP-D 104. LOWNDES CO.: Collected in spring just S of Lowndes County Rd. 40 (32.325966°N, 86.681629°W; WGS 84). 10 February 2008. S. Graham and S. Hoss. AUM 37643.

Anura – Frogs

Acris crepitans (Northern Cricket Frog). BULLOCK CO.: Collected AOR Bullock County Road 14 at the Conecuh River (32.010724°N, 85.740373°W; WGS 84). 29 December 2007. S. Graham and S. Hoss. AUM 37613. LAMAR CO.: Collected DOR on Lamar County Rd. 12 (33.579901°N, 88.0989721°W; WGS 84). 12 February 2008. S. Graham and S. Hoss. AUM 37644.

Acris gryllus (Southern Cricket Frog). CRENSHAW CO.: Collected DOR on Crenshaw County Rd. 1200 m NW Crenshaw County Rd. 7 (31.700153°N, 86.375061°W; WGS 84). At least one male also heard calling at this locality on this night (large beaver marsh N of road). 10 December 2008. S.Graham, R. Birkhead, and K. Gray. AHAP-D 180–181.

Anaxyrus fowleri (Fowler's Toad). CRENSHAW CO.: Found at US Hwy 331 at the Conecuh River (31.574056°N, 86.253057°W; WGS 84). 02 October 2008. S. Graham, D. Steen, and K. Gray. AHAP-D 149.

Anaxyrus terrestris (Southern Toad). CRENSHAW CO.: Collected DOR on State Rt. 106 (31.604150°N, 86.414700°W; WGS 84). 10 December 2008. S. Graham, R. Birkhead, and K. Gray. AHAP-D 173. MONROE CO.: Collected AOR on Monroe County Rd. 47 (31.815335°N, 86.959945°W; WGS 84). 22 September 2007. S. Graham and S. Hoss. AHAP-D 80

Gastrophryne carolinensis (Eastern Narrow-mouthed Toad).

Conecuh Co.: In seepage 5m N of State Rt. 106 (31.707310°N, 86.929000°W; WGS 84). 5 May 2008. R. Birkhead and S. Graham. AHAP-D 190. Crenshaw Co.: Found at US Hwy 331 at the Conecuh River (31.574056°N, 86.253057°W; WGS 84). 2 October 2008. S. Graham, D. Steen, and K. Gray. AHAP-D 150. Lowndes Co.: Collected AOR Lowndes County Rd. 40 (32.327441°N, 86.743206 °W; WGS 84). 03 September 2007. S. Graham AHAP-D 75.

Hyla avivoca (Bird-voiced Treefrog). Lowndes Co.: Collected DOR on Lowndes County Rd. 40, 0.64 km E of Cypress Cr. bridge (32.331069°N, 86.669781°W; WGS 84). 18 October 2007. S. Graham. AUM 37570.

Hyla chrysoscelis (Cope's Gray Treefrog). Bullock Co.: Collected AOR on Bullock County Rd. 23, 0.8 km NW of US Hwy 82 (32.17664122°N, 85.7088937°W; WGS 84). 10 July 2008. S. Graham. AHAP-D 130–131. Crenshaw Co.: Collected DOR State Rt. 59 N of Patsburg (31.790033°N, 86.229567°W; WGS 84). 10 December 2008. R. Birkhead, S. Graham, and K. Gray. AHAP-D 179. Cullman Co.: Found along millpond at Clarkson-Legg covered bridge (34.207298°N, 86.990100°W; WGS 84). 11 July 2008. S. Graham, M. Connell, D. McMoran, K. Gray. AHAP-D 141. Lamar Co.: Collected DOR on Lamar County Rd. 12 (33.572793°N, 88.212234°W; WGS 84). 29 November 2008. S. Graham and K. Gray. AHAP-D 165.

Hyla cinerea (Green Treefrog). Butler Co.: Collected DOR on State Rt. 106, 0.8 km W of Butler County Rd. 7 (31.665940°N, 86.856180°W; WGS 84). 18 October 2007. S. Hoss and A. Liner. AUM 37581. Crenshaw Co.: Collected AOR on State Rt. 106 (31.589400°N, 86.396317°W; WGS 84). 10 December 2008. S. Graham, R. Birkhead, and K. Gray. AHAP-D 172. Cullman Co.: Found along millpond at Clarkson-Legg covered bridge (34.207298°N, 86.990100°W; WGS 84). 11 July 2008. S. Graham, M. Connell, D. McMoran, K. Gray. AHAP-D 140. Lowndes Co.: Collected DOR Lowndes County Rd. 29/40 intersection (32.33260°N, 86.646066°W; WGS). 3 September 2007. S. Graham. AUM 37476. Lamar Co.: Collected AOR Lamar County Rd. 12 (33.578240°N, 88.111256°W; WGS 84). 10 January 2008. S. Graham. AHAP-D 101.

Hyla femoralis (Pine Woods Treefrog). Marengo Co.: Collected on Marengo County Rd. 30 200m W of railroad at Magnolia Terminal. 1 August 1976. J. Autery. AUM 29665.

Hyla gratiosa (Barking Treefrog). Crenshaw Co.: Collected AOR on US Hwy 29 SW Brantly (31.577350°N, 86.281700°W; WGS 84). 10 December 2008. S. Graham, R. Birkhead, and K. Gray. AHAP-D 173. Lowndes Co.: Collected AOR on Lowndes County Rd. 40 (32.326992°N, 86.702447°W; WGS 84). 18 October 2007. S. Graham AHAP-D 66.

Hyla squirella (Squirrel Treefrog). Lowndes Co.: Collected AOR on Lowndes County Rd. 40 (32.331811°N, 86.657170°W; WGS 84). 21 September 2007. S. Graham, S. Hoss, D. Steen, V. Johnson. AHAP-D 79. Monroe Co.: Collected DOR on State Rt. 21 6.12 km N of State Rt. 47 bypass (31.570260°N, 87.285750°W; WGS 84). 18 October 2007. S. Hoss and A. Liner. AUM 37580.

Lithobates catesbeianus (American Bullfrog). Lowndes Co.: Collected AOR on Lowndes County Rd. 40 (32.331925°N, 86.649499°W; WGS 84). 21 September 2007. S. Graham, S. Hoss, D. Steen, and V. Johnson. AHAP-D 78.

Lithobates clamitans (Green Frog). Colbert Co.: Along Cane Creek in Cane Creek Canyon Nature Preserve (34.626323°N, 87.805596°W; WGS 84). 13 September 2008. D. Steen, S. Graham, C. Guyer, and K. Bakkegard. AHAP-D 144. Cullman Co.: Found along millpond at Clarkson-Legg covered bridge (34.207298°N, 86.990100°W; WGS 84). 11 July 2008. S. Graham, M. Connell, D. McMoran, K. Gray. AHAP-D 188. Dale Co.: Collected DOR on Dale County Road 19 100m from State Rt. 123 (31.5711208°N, 85.6722654°W; WGS 84). 29 December 2007. S. Graham and S. Hoss. AHAP-D 185–186. Hale Co.: Found AOR on Hale County Rd. 50 ~ 2km E of intersection with Hale County Rd. 44 (32. 966308°N 87.546789°W; WGS 84). 20 September 2008. S. Graham and K. Gray. AHAP-D 161. Lamar Co.: Collected DOR on Lamar County Rd. 12 adjacent to Fernbank Baptist Ch. (33.578645°N, 88.140127°W; WGS 84). 12 February 2008. S. Graham and S. Hoss. AUM 37645. Lowndes Co.: Collected AOR on Lowndes County Rd. 40 (32.331842°N, 86.648872°W; WGS 84). 3 September 2007. S. Graham. AHAP-D 76.

Lithobates palustris (Pickerel Frog). Cullman Co.: Found under Clarkson-Legg covered bridge (34.207298°N, 86.990100°W; WGS 84). 11 July 2008. S. Graham, M. Connell, D. McMoran, K. Gray. AHAP-D 143.

Lithobates sphenocephalus (Southern Leopard Frog). Bullock Co.: Found DOR Bullock County Road 14 at the Conecuh River (32.010724°N, 85.740373°W; WGS 84). 29 December 2007. S. Graham and S. Hoss. AUM 37610. Crenshaw Co.: Collected along west bank of Conecuh River at Crenshaw County Rd. 77 (31.487593°N, 86.361388°W; WGS 84). 4 October 2008. S. Graham, D. Steen, and K. Gray. AHAP-D 152. Lamar Co. Collected AOR St. Route 96 SW of Belk, AL (33.616678°N, 87.954633°W; WGS 84). 10 January 2008. S. Graham. AHAP-D 102. Lowndes Co.: Found AOR on Lowndes County Rd. 40 (32.327348°N, 86.710297°W; WGS 84). 18 October 2007. S. Graham. AHAP-D 65. Pike Co.: Collected DOR on US Hwy 231, 0.16km N of intersection with State Rt. 125 (31.681467°N, 85.824700°W; WGS 84). 10 December 2008 S. Graham, R. Birkhead, and K. Gray. AHAP-D 182.s

Pseudacris crucifer (Spring Peeper). Bullock Co.: Found AOR Bullock County Road 35 (32.029348°N, 85.588407°W; WGS 84). 29 December 2007. S. Graham and S. Hoss. AHAP-D 183. Coffee Co.: Collected AOR on State Rt. 189 0.5 km E of Crenshaw County Line (31.524867°N, 86.189500°W; WGS 84). 10 December 2008. S. Graham, R. Birkhead, and K. Gray. AHAP-D 174. Conecuh Co.: Collected DOR on State Rt. 106 0.1 km E of Conecuh County Rd. 37 and State Rt. 106 intersection (31.706196°N, 86.921304°W; WGS 84). 17 October 2008. S. Graham and K. Gray. AUM 37828. Dale Co.: Found AOR Dale County Road 36 E of Ozark, AL (31.461183°N, 85.579572°W; WGS 84). 29 December 2007. S. Graham and S. Hoss. AHAP-D 184. Fayette Co.: Collected DOR Fayette County Rd. 12 at the Sipsey River (33.543883°N, 87.784320°W; WGS 84). 12 February 2008. S. Graham and S. Hoss. AUM 37646. Lamar Co. Collected AOR St. Route 96 SW of Belk, AL (33.616678°N, 87.954633°W; WGS 84). 10 January 2008. S. Graham. AHAP-D 100. Lowndes Co.: Collected AOR on Lowndes County Rd. 40 (32.326603°N, 86.680310 °W; WGS 84). 18 November 2007. S. Graham and K. Gray. AHAP-D 67. Pickens Co.: Collected DOR State Rt. 17 N of Reform (33.511498°N,

87.980888°W; WGS 84). 29 November 2008. S. Graham and K. Gray. AHAP-D 166.

Pseudacris feriarum (Upland Chorus Frog). Crenshaw Co.: Collected in roadside ditch along Bradleyton Rd. (31.880455°N, 86.250700°W; WGS 84). Several males heard chorusing. 10 December 2008. R. Birkhead, S. Graham, and K. Gray. AHAP-D 171. Dale Co.: Collected in roadside ditch off Dale County Rd. 59 0.6 km NW of Choctawhatchee River (31.478963°N, 85.537040°W; WGS 84). Several males heard chorusing. 29 December 2007. S. Graham and S. Hoss. AHAP-D 187. Lamar Co.: Collected AOR on Lamar County Rd. 12 .80 km E of Mississippi State Line (33.574091°N, 88.262090°W; WGS 84). 29 November 2008. S. Graham and K. Gray. AHAP-D 164.

Scaphiopus holbrookii (Eastern Spadefoot). Bullock Co.: Collected AOR on Bullock County Rd. 40 3.22 km E of Union Springs (32.167561°N, 85.612993°W; WGS 84). 10 July 2008. S. Graham. AHAP-D 132. Dale Co.: Found DOR Dale County Road 36 (31.462133°N, 85.576611°W; WGS 84). 29 December 2007. S. Graham and S. Hoss. AUM 37611.

Testudines – Turtles

Chelydra serpentina (Snapping Turtle). Covington Co.: Found AOR on US Hwy 29 (31.455568°N, 86.433406°W; WGS 84) 3.56 km SW of Covington County Line. 18 March 2008. S. Graham. AHAP-D 107. Lauderdale Co.: Found in Little Cypress Cr. at Lauderdale County Rd. 8 (34.949325°N, 87.694589°W; WGS 84). 12 July 2008. S. Graham, M. Connell, D. McMoran, and K. Gray. AHAP-D 143. Macon Co.: Captured in hoop trap in large beaver marsh in Tuskegee National Forest (32.428926°N, 85.647345°W; WGS 84). 19 June 2008. S. Graham and M. Connell. AHAP-D 129.

Terrapene carolina (Eastern Box Turtle). Cullman Co.: Found under Clarkson-Legg covered bridge (34.207298°N, 86.990100°W; WGS 84). 11 July 2008. S. Graham, M. Connell, D. McMoran, K. Gray. AHAP-D 142.

Squamata – Lizards

Anolis carolinensis (Green Anole). Crenshaw Co.: Collected DOR on Crenshaw County Rd. 59 (31.751883°N, 86.232050°W; WGS 84). 10 December 2008. R. Birkhead, S. Graham, and K. Gray. AHAP-D 177–178.

Plestiodon laticeps (Broad-headed Skink). Crenshaw Co.: Found at US Hwy 331 at the Conecuh River (31.574056°N, 86.253057°W; WGS 84). 2 October 2008. S. Graham, D. Steen, and K. Gray. AHAP-D 146-148.

Scincella lateralis (Little Brown Skink). Hale Co.: Payne Lake Recreational Area, Talladega National Forest. Near spring W of Lake. (32.886059°N, 87.445250°W; WGS 84). 20 September 2008. S. Graham and K. Gray. AHAP-D 160.

Squamata – Snakes

Agkistrodon contortrix (Copperhead). Crenshaw Co.: In Threemile Creek floodplain ~ 25 m E of US Hwy 29 (31.520517°N, 86.335433°W; WGS 84). 04 October, 2008. S. Graham, K. Gray, and D. Steen. AHAP-D 153. Cullman Co.: Found DOR on Cullman County Rd. 1043 100 m E of Winston County Line (34.228753°N, 87.109102°W; WGS 84). 12 April 2008. S. Graham. AHAP-D 121.

Carphophis amoenus (Eastern Wormsnake). Conecuh Co.: In seepage 5 m N of State Rt. 106 (31.707310°N, 86.929000°W; WGS 84). 05 May 2008. R. Birkhead and S. Graham.

Coluber constrictor (North American Racer). Lowndes Co.: Collected DOR Lowndes County Rd. 40 (32.327227°N, 86.762491°W; WGS 84). 03 September 2007. S. Graham. AUM 37480. Wilcox Co.: Collected in small branch 5 m S of Howard Steen Rd. (31.884617°N 96.922506°W; WGS 84). 5 May 2008. R. Birkhead and S. Graham. AHAP-D 98.

Crotalus horridus (Timber Rattlesnake). Lowndes Co.: Collected DOR Lowndes Wildlife Management Area, 200 m W of Check Station turnoff (32.364884°N, 86.740857°W; WGS 84). 03 September 2007. S. Graham. AUM 37478.

Diadophis punctatus (Ring-necked snake). Hale Co.: Payne Lake Recreational Area, Talladega National Forest. In swampy area S of dam (32.878206°N, 87.443716°W; WGS 84). 20 September 2008. S. Graham and K. Gray. AHAP-D 158. Lowndes Co.: Collected AOR Lowndes County Rd. 40 (32.326305°N, 86.680024°W; WGS 84). 21 November 2007. S. Graham. AHAP-D 71.

Lampropeltis getula niger (Eastern Black Kingsnake). Limestone Co.: Found along Limestone Cr. 5 m S of Interstate Hwy 565 (34.648517°N, 86.822358°W; WGS 84). 12 July 2008. S. Graham, M. Connell, D. McMoran, and K. Gray. AHAP-D 189.

Masticophis flagellum (Eastern Coachwhip). Elmore Co.: DOR State Rt. 229, 4.83 km S of Tallassee (32. 493624°N, 85.892708°W; WGS 84). 05 May 2009. R. Birkhead. AHAP-D 204.

Nerodia erythrogaster (Plain-bellied Watersnake). Lowndes Co.: Collected DOR Lowndes County Rd. 40 (32.326305°N, 86.680024°W; WGS 84). 21 November 2007. S. Graham. AHAP-D 70.

Opheodrys aestivus (Rough Greensnake). Lowndes Co.: Collected DOR 8.85 km W of Montgomery County line at Tallawassee Creek bridge over Lowndes County Rd. 40 (32.329826°N, 86.557229°W; WGS 84). 18 October 2007. S. Graham. AUM 37572.

Pantherophis guttatus (Red Cornsnake). Covington Co.: Found DOR on US Hwy 331 at mile marker 10. 2 October 2008. S. Graham, D. Steen, and K. Gray. AHAP-D 151. Elmore Co.: Found DOR Elmore County Road 4 (32.451117°N, 86.075117°W; WGS 84). 17 September 2008. S. Graham and R. Birkhead. AHAP-D 191.

Pantherophis spiloides (Gray Ratsnake). Chilton Co.: Found DOR on US Hwy 82 3.22 km N of Autauga County Line (32.683793°N, 86.791322°W; WGS 84). 30 November 2008. S. Graham. AHAP-D 164. Lowndes Co.: Collected DOR in Lowndes WMA 0.8 km E of Check Station (32.350679°N, 86.725180°W; WGS 84). 21 September 2007. S. Graham, V. Johnson, D. Steen and S. Hoss. AUM 37491.

Storeria dekayi (DeKay's Brownsnake). Bullock Co.: Found AOR on US Hwy 82 N of Union Springs (32.175567°N, 85.709517°W; WGS 84). 10 December 2008. S. Graham, R. Birkhead, and K. Gray. AHAP-D 175. Conecuh Co.: Collected DOR on State Rt. 106 1.45 km E of County Rd. 29 intersection (31.707533°N, 86.933592°W; WGS 84). 17 February 2008. S. Hoss. AUM 37650. Hale Co.: Payne Lake Recreational Area, Talladega National Forest. In spring W of lake. (32.878206°N, 87.443716°W; WGS 84). 20 September 2008. S. Graham and K. Gray. AHAP-D 159. Lowndes Co.: Collected AOR Lowndes County Rd. 40 (32.327649°N, 86.743344°W; WGS 84). 03 September 2007. S. Graham. AHAP-D 74. The Conecuh and Lowndes county records fill a substantial distribution gap from the nearest documented populations to the N (Bibb County) and NE (Montgomery County) to those to the SW (Washington County; Mount 1975).

Storeria occipitomaculata (Redbelly Snake). Henry Co.: Collected in swamp S of Hutto Pond, 4.61 air km W of Laurenceville (31.660815°N, 85.317152°W; WGS 84). 13 May 2009. S. Graham and D. Laurencio. AUM 34915.

Thamnophis sauritus (Eastern Ribbonsnake). Crenshaw Co.: Collected DOR on Crenshaw County Rd. 1, 200m NW Crenshaw County Rd. 7 (31.700153°N, 86.375061°W; WGS 84). 10 December 2008. S.Graham, R. Birkhead, and K. Gray. AHAP-D 169. Lowndes Co.: Collected DOR on Lowndes County Rd. 40 (32.331976°N, 86.594544 °W; WGS 84). 21 September 2007. S. Graham, S. Hoss, D. Steen, V. Johnson. AUM 37490. St. Clair Co.: Found under rock next to small creek along US Hwy 231 ~ 10 km S of Ashville (33.754353°N, 86.275546°W; WGS 84). 2 March 2008. S. Graham and S. Hoss. AHAP-D 103.

Thamnophis sirtalis (Common Gartersnake). Lowndes Co.: Collected DOR on Brownshill Rd. 100 m W of Lowndes County Rd. 40 (32.318552 °N, 86.577542 °W; WGS 84). 3 September 2007. S. Graham AUM 37477.

Acknowledgments.—We thank Craig Guyer for verifying these records. We thank V. Johnson, D. J. McMoran, M. Connell, K. Bakkegard, and A. Liner for their assistance during these field trips, and J. Autery for his contributions. These collection trips were partially supported by NIH grant R01-A149724 to T. Unnasch under ADCNR Permit 4268.

Lizards have become a model group for research spanning a wide range of biological disciplines, including: morphology, physiology, ecology, behavior, and evolution. Over the past 40 years, many of the advances in lizard ecology have been periodically summarized in books beginning with the title *Lizard Ecology*. These include: *Lizard Ecology: A Symposium* (Milstead 1967), *Lizard Ecology: Studies of a Model Organism* (Huey et al. 1983), and *Lizard Ecology: Historical and Experimental Perspectives* (Pianka and Vitt 1994). The most recent addition, *Lizard Ecology: The Evolutionary Consequences of Foraging Mode* adds to this lineage and provides further evidence of the importance of lizards in understanding the evolutionary complexity and trade-offs inherent in the way animals forage for their food. At its core, *Lizard Ecology* focuses on the sit-and-wait (SW)/ambush mode of foraging versus the active, widely-foraging (WF) dichotomy (analogous to the r-K dichotomy of life history theory), where species are lumped into one or other foraging mode (FM). In the latest release, researchers have tested an immense range of hypotheses from the fields of ecology, evolutionary biology, and animal behavior using species with an equally diverse range of natural histories. The goal of the book is to review research on FM and assess its influence on the biology of squamates that has accumulated over the past 40 years. The book is divided into two parts: I. Organismal patterns of variation in FM, and II. Environmental influences of FM. The first 11 chapters make up Part I and include relationships between FM and various aspects of squamate biology, such as physiology, morphology, anatomy, performance, behavior, diet and life history. Part II centers around the influence of nocturnality (geckos) on FM, plasticity in FM in response to environmental variation, and habitat use and its relationship to food acquisition.

To begin, Ray Huey and Eric Pianka provide interesting insight into the emergence of the term FM (Pianka 1966). Following on in one of the most important chapters (Chapter 1), particularly

in terms of data collection and quality, Gad Perry examines and identifies the all-too-often neglected issues of methodology and terminology of foraging behavior. This is followed by theoretical predictions of foraging theory. Measuring foraging behavior, and the qualitative versus quantitative measures of speed, moves per minute and percentage time spent moving has often been problematic and there has rarely been consensus on how such foraging behaviors should be measured. Perry examines various taxonomic groups to determine the number of observations necessary to reliably estimate foraging behavior. In general, we find that, with the exception of gekkonid lizards, relatively few samples (≥15) are needed to reliably estimate a species' movement rates.

Early predictions of foraging mode suggested "SW" foragers should have high sprint speed and low endurance, highlighting an evolutionary trade-off. In the longest chapter of the book (Chapter 2; 45 pages), Miles et al. use published data on sprint speed, endurance and FM to examine these hypotheses, and provide a macroevolutionary perspective on whether morphology and locomotor performance correlates with FM, using size-corrected data for the majority of lizard groups. Finally, they examine data within *Anolis* to provide a microevolutionary perspective using field data on foraging behavior and locomotor performance in the field. Nonetheless, their ancestral reconstruction reveals that shifts in FM from SW-WF occurred early in the evolution of squamate reptiles, probably at the node of scleroglossans, as other studies have suggested (e.g., Vitt and Pianka 2005). One result to emerge is that SW species have greater sprint speeds than WF species. In closing, the authors warn against categorizing SW-WF as end points of a continuum, but instead encourage the collection of additional data to develop a clearer picture of the differences in foraging behavior.

In Chapter 3, correlates of lizard foraging mode, Kevin Bonine highlights known and potential correlations between physiology and performance traits that relate primarily to FM. Using Arnold's (1983) paradigm (morphology → performance → behavior → fitness) he presents results within a phylogenetic context to explore the link between morphology and performance. In addition, Bonine provides a thorough introduction to FM and physiology, and whole-animal performance measures, including energy balance, sprint speed, endurance, temperature, water loss, aerobic capacity, anaerobic scope, and the sub-organismal physiological traits of respiration and muscle physiology.

Chapter 4 (Brown and Nagy) addresses the fundamental ecological question: do WF species have greater energetic costs than SW species? The authors use published data on field metabolic rates (FMR), and doubly labeled water (DLW) for 46 lizard species, develop allometric equations for members of each FM, which they use to assess the position of new species, and to predict, develop and test bioenergetic hypotheses. They begin by reviewing older studies that examined distantly related SW-FW species, and move onto more recent studies which focus on more closely related species. Next, they examine DLW studies in an attempt to detect general patterns among SW and FW species, before examining the phylogenetic effects of energy use among lacertilians. While their results for the FMR data support the SW-FW dichotomy they suggest that as more foraging behavior data become available, it may be possible to use a continuous predictor (e.g., MPM) to investigate patterns in FM and energy use.

In Chapter 5 the modern-day fathers of lizard ecology, Laurie Vitt and Eric Pianka begin with the admission that… "the foraging mode paradigm is more complex than originally envisioned" (page 141). Fittingly, their chapter sets out to highlight major evolutionary and non-evolutionary factors that affect the prey types consumed by lizards, using diet data for 184 lizard species from Africa, Australia, North America and the New World Tropics. They begin by presenting factors likely to influence the prey consumed by lizards in addition to foraging mode, including; body size, biomechanics of feeding structures, thermoregulatory behavior, times of activity, sensory capabilities, physiological constraints, and resource availability. The results of their phylogenetic analyses revealed that variation among lizard diet is reduced by 80%, suggesting many of the differences are nested deep within the evolutionary history of lizards. The emergence of chemical prey discrimination, jaw prehension, and the use of a WF mode of locomotion to find prey, no doubt led to an increase in prey types that were unavailable previous to iguanians. The sheer number of extant scleroglossans (snakes and lizards; 6000) to iguanians (1230) provides ample evidence for the success of these evolutionary innovations.

In Chapter 6 Shine and Wall examine the reasons for the dramatic degree of intraspecific niche divergence in body size and sex observed in snakes compared to lizards. To begin, the authors highlight a series of mechanisms that may drive observed patterns of: size-dependent shifts in prey consumption, and intersexual niche divergence, including other factors that may cause variation in foraging traits within a species. In the final part of their chapter, the authors highlight the difference between lizards and snakes (e.g., snakes consume a wider range of prey sizes), and follow this with a series of hypothesis that test these ideas. The authors suggest that the functional basis for the intraspecific shift in dietary niche frequently observed in snakes relates mainly to differences in the anatomy, physiology, ecology and behavior observed between snakes and lizards.

Anthony Herrel (Chapter 7) aims to identify those traits (ecological, morphological and performance) in lizards that are typically associated with the two foraging modes, and compares these with the traits typically associated with an herbivorous lifestyle. One of the highlights of this chapter is the finding that ancestry appears not to have constrained the dietary mode of lizards. Regardless of FM the shift to herbivory has led to the evolution of flat, blade-like teeth, high bite force, large size and a longer colon. Moreover, given that these traits are present within omnivorous species, it suggests that the evolutionary shift to herbivory has occurred via an omnivorous diet. Given this, Herrel poses the question of why are their so few scleroglossan herbivores? Clearly, this is one question requiring additional data!

In Chapter 8, William Cooper describes the morphology and physiology of lizard chemosensory systems, the evidence for prey chemical discrimination, and how lizard FMs have influenced these relationships. Evidence is presented in the form of correlated evolution between the lingual-vomeronasal system, food chemical discrimination, and FM. We find that differences in FM have influenced the evolution of diet, and this has then affected the responsiveness of species to the different chemicals of specific food types. In closing, Cooper discusses the role of the lingual-vomeronasal system and foraging mode, for prey chemical discrimination, and

in driving the evolutionary diversification of lizards.

In Chapter 9 McBrayer and Corbin examine patterns of head shape variation in response to FM, in order to establish the existence of trade-offs between head shape, biting force, and FM using 22 species of lizard representing 12 families. Here we find that head length and width has evolved in concert with FM, but that much remains to be learned. In particular, it is unclear whether head shape is changing in response to foraging mode alone, or whether other forces play a part. Following on, Reilly and McBrayer (Chapter 10) examine the convergence and divergence in prey capture and processing behavior and the evolution of lingual and sensory traits in lizards. In general, three distinct patterns of FM emerge: two distinct SW predators, one mixed forager, and thee distinct WFs. They suggest that despite the similar prey processing behaviors of the Iguania and Gekkota, it is achieved via fundamentally different forms of tongue use when capturing prey. The mixed FM and retention of primitive Autarchoglossan features and tongue prehension place the Scincoidea midway. Indeed, the evolution of a tongue with chemosensory abilities appears to have been a pre-determinate of a widely-foraging strategy and is probably a key component of the WF vs. SW FM dichotomy.

Beaupre and Montgomery (Chapter 11) change gear by focusing on the FM of snakes, with reference to interspecific and broad-scale patterns among snakes. They point out that the foraging modes of snakes differ from that of lizards by being strongly determined by phylogeny: species within the same family tend to forage in a similar way, with relatively few exceptions. The authors consider an impressive range of factors likely to influence snake foraging mode. There is evidence, however, that snake foraging modes conform to the "syndrome hypothesis" by being sufficiently variable. Results from a bioenergtic model suggest that within snakes the dichotomous classes of FM may represent adaptive peaks, with intermediate FMs favored only under certain conditions. In closing, it becomes clear that a suitable definition of FM for snakes is lacking.

In Chapter 12 Aaron Bauer examines a group that appears to be an exception to the SW–WF dichotomy, the Gekkota. The Gekkota contain some 1100+ species representing 106 genera from essentially three families. A large summary table (7 pages) provides details of the genera, number of species and FM. The Gekkota display a mixed foraging strategy, and provide some evidence that WF evolved with the Scleroglossa, and was probably facilitated by the development of chemosensory abilities. Thus, despite similar chemosensory abilities as autarchoglossans, the Gekkotans moved along an alternative evolutionary pathway for foraging, having retained visual predation and SW foraging. However, apart from this generality little more can be concluded. Thus, while geckos do not fall neatly into the dichotomous foraging paradigm, Bauer concedes that more data (movement patterns, additional lineages, etc.) are necessary to provide greater confirmation on this placement.

In Chapter 13 Martin Whiting examines plasticity in FM using the lizard *Platysaurus broadleyi* – a member of a clade of SW foragers which shows considerable variation in FM. For instance, juveniles move more in order to hunt insects, while adults move less often making short movements, but switch to active "herbivory" in order to increase the likelihood of encountering figs when available. This provides a clear fitness benefit in situations where a high quality resource becomes available, but which requires a different FM then that which is typically employed. Indeed, whether lizards experience a trade-off between the amount of time spent foraging and courtship/reproducetive behavior, or simply increase energy intake, is unknown—and a question in need of study. In closing, Whiting posses two questions highlighted by the *Platysaurus* system: 1. how widespread is FM plasticity and what is the effect of a spatially and temporally variable high energy resource on FM? and 2. what effect on FM does having traits common to both ambush and active foragers? Clearly, there awaits considerable research potential for such a system!

In Chapter 14 Vanhooydonck et al. provide insight into the relationship between locomotor performance, bite performance and head morphology of lacertid lizards. They investigate how endurance and sprint performance affect an organism's feeding ecology, and whether there is a trade-off between species that rely on sprint performance to acquire prey versus species that are reliant on increased stamina for prey capture. The results suggest endurance and the proportion of soft-bodied prey consumed is co-evolved in lacertid lizards. However, speed is not correlated with evasive prey, but rather with the proportion of intermediate prey in the diet. In males, body flattening and climbing trade-off is due to a reduction in head height, which is likely to be beneficial for maintaining the center of mass close to the substrate (Aerts et al. 2003), and reducing the possibility of the animal lifting off the substrate. Conversely, there iss no trade-off between body flattening and climbing in females, possibly because of differential selection on head shape in males versus females.

In Chapter 15 Roger Anderson examines FM from the perspective of the principal ecological features required by any organism to survive: finding food, avoiding becoming food, avoiding abiotic extremes (e.g., temperature), and reproducing. Anderson examines how food acquisition mode (FAM), as opposed to FM *per se*, varies among lizards, and among habitats. Unfortunately, the message from this chapter is that we still know too little to conclude much regarding the role of FAM on the evolution of lizard FM. Nonetheless, Anderson proposes promising possibilities for future research, such as the use of laboratory microcosms and semi-natural mesocosms for conducting experimental tests of FAM, prey types, competitors and predators.

In the shortest chapter (Chapter 16) Vitousek et al. examine the Galapagos Marine Iguana, whose short, intense bouts spent foraging on macrophytic marine algae are unique among reptiles, and more reminiscent of a SW foraging style. They the marine iguana as a model system to test how natural and sexual selection drive morphological and behavioral adaptation, including the physiological and environmental constrains that act as intense selective pressures on this species. We find that in response to the strong selective pressures of their energetically costly grazing bouts, marine iguanas have evolved a blunt head, salt glands, and dark coloration allow for maximal energy intake.

In Chapter 17 McBrayer et al. summarize by highlighting those studies to emerge since Huey and Pianka (1981). They point out that while many traits relate to foraging mode, there remain many areas in need of additional research attention. The authors suggest that because FM span both physiological and morphological parameters there is a need for more integrative approaches and thinking; only in this way can both general patterns and variation in lizard foraging biology be understood.

In closing, *Lizard Ecology* brings together a diverse range of information, offering a great starting point for anyone contemplating lizard studies likely to incorporate aspects of food acquisition and foraging behavior. Presumably, this is because it achieves its main goal by determining the influence of FM on the biology of squamate reptiles. Overall, the book contains few errors, a complement to the three editors. While some may lament the lack of color images, the text is well complemented with numerous tables (37), and figures (90). On the downside, however, the book is highly priced (US $142), and may be out of reach for students or people with just a general interest in lizard ecology. Price not withstanding, this work is a worthy acquisition for anyone interested in lizard ecology and behavior. As stated by Kevin Bonine in Chapter 3, the success of books of the *Lizard Ecology* series (Milstead 1967; Huey et al. 1983; Pianka and Vitt 1994), and the recent *Lizards: Windows to the Evolution of Diversity* (Pianka and Vitt 2003) highlight the appeal of lizard biology to scientists and a wider audience alike.

The new book *Ecological and Environmental Physiology of Amphibians* provides an up-to-date and relatively concise summary of comparative research on amphibian physiology. This is the first volume in the Ecological and Environmental Physiology Series published by Oxford University Press; similar volumes are in the works for reptiles, fishes, birds, insects, and crustaceans (http://www.eeps-oxford.com). One may wonder whether this review is necessary following the relatively recent synthesis edited by Feder and Burrgren (1992). However, this new book fills a different niche and is more appropriate for those looking for a concise review, especially students. This multi-authored book provides a relatively well-integrated and cohesive view of the topic that should prove accessible to researchers, graduate students, and those teaching courses in physiology or amphibian biology. While Hillman and co-authors touch on many aspects of amphibian physiology, the book places a particular emphasis on water balance, an obviously important topic for amphibians and a dominant area of expertise of the authors. This book will serve as a useful and up-to-date addition to the much larger volume by Feder and Burggren (1992).

Most importantly, this book will serve as an entry point for students and researchers interested in integrating a physiological component into their comparative and phylogenetic studies. While not as all encompassing as Feder and Burggren (1992), Hillman et al. succeed in producing a work is perhaps a more engaging introduction to amphibian physiology. This book provides references to and short summaries of relevant literature published since 1992, especially for some topics such as metabolic depression. It also provides gems for young physiologists and comparative biologists interested in unusual features of amphibians, such as the sections dealing with cutaneous water exchange (including "waterproof" frogs in *Chiromantis* or *Phyllomedusa*), the physiology of the "pelvic" or "seat" patch, cocoon formation, dehydration tolerance, and hypoxia.

The book is organized into six chapters: an introduction with a discussion of diversity, phylogeny, and basic physiological challenges faced by amphibians; two chapters summarizing both basic and specialized aspects of amphibian physiology; a chapter on the

physiology of species living in "extreme" environments; and two final short chapters, one detailing approaches and techniques and the other on future directions. I found the separation of chapters into basic, specialized, and "extreme" physiology to be a useful division that highlights the physiology of unusual taxa living in deserts or regions with freezing soils. The section concerning techniques in amphibian physiology provides a quick introduction to oft-used methods and the inclusion of some historical background for some methods is a nice touch.

The section on cardiovascular oxygen and carbon dioxide exchange (2.6) is probably my favorite. In many ways, it is representative of the many positive aspects of this book and its utility for those requiring an informed yet brief introduction. This section includes reviews of cardiovascular anatomy and basic physiology, and has a number of short, readable passages on topics such as arterial pressure, mixing of pulmocutaneous and systemic flows, and cardiac output.

This basic summary and introduction to the relationship between physiology and ecology will be of interest to audiences other than physiologists, such as those interested in ecological niche modeling. The chapter on physiological adaptations to extreme environments provides interesting food for thought for those considering how environmental variables contribute to determining species distributions. There is a general lack of knowledge about where amphibians actually spend their time (e.g., in trees, under ground, and high up or far down), but this book engenders an appreciation that this likely has important physiological consequences. There is also a fair amount of physiological variation between species, for instance in the ability to "supercool" which would effect species distributions. Basic data on the relationship between physiology and ecology is also important to evolutionary studies of the relationship between morphology and the environment, which, for example, has been relatively little explored in frogs, especially the Neobatrachia.

In a relatively short review of a topic as large and varied as amphibian physiology, there are inevitably many areas that receive little attention; examples include endocrinology, development, or locomotory and behavioral energetics. Despite the focus on the relationship between physiology and the environment, the mention of phenotypic plasticity is limited to an exceedingly brief discussion of developmental rates. Studies on plasticity and reaction norms can form a beneficial basis for many research programs (e.g., Schlichting and Pigliucci, 1998; West-Eberhard, 2003), including those on amphibian physiology. There are several short sections on larval physiology (e.g., energy budgets, skin morphology), but, in general, there is little attention paid to larvae or metamorphosis. For those interested in these topics, I suggest turning to the thorough review by Burggren and Just (1992).

I appreciated that many of the flow charts summarizing available data contain references pointing to appropriate literature. Summary tables, such as Table 2.2, are very useful and help to drive home the lack of knowledge for most species. Many of the plots and flow charts will prove useful as teaching aids, though some drawings and photographs could be of higher quality (e.g., Figs. 2.37, 3.41, 4.6A, 5.10).

The first chapter of this work lays out a comparative framework that aims to encapsulate all living amphibian diversity, including a lengthy section titled "Habitats and Morphotypes." While some discussion does appear in the literature (e.g., Emerson, 1988), to my knowledge, such a detailed and explicit discussion of amphibian morphotypes has not been published previously in a form that is easily accessible to students. The authors state that the discussion of morphotypes is intended to refine the traditional categories of aquatic, fossorial, terrestrial, and arboreal. However, the categories proposed by the authors will need further scrutiny as some are separated by few substantial differences. For example, imagine trying to teach the difference between "semi-aquatic" and "semi-terrestrial (mesic)"; the only character state given that differs between these morphotypes is the amount of webbing (fully webbed vs. not fully webbed). This is a good start, but further quantitative studies of morphotypes will be necessary. One drawback is that the relationship between morphotypes and environment is not adequately explored using comparative methods. Morphotypes are summarized by family in Table 1.1 (with the number of species examined in parentheses; R. Drewes, pers. comm.), but it is only much later in the book (p. 377) that the often extensive variation within families and genera is clearly pointed out. However, this review of morphotypes still provides a concise summary for students and is a satisfactory start at dissecting ecomorphological diversity within the three orders of living amphibians.

At the time of the last thorough synthesis of environmental physiology of amphibians (i.e., 1992), the described diversity of amphibians was considerably less (~ 70% of the diversity recognized at the time of writing this review; D. Frost, pers. comm.) and a central problem confounding comparative research was the lack of phylogenetic data. Yet descriptions of new species and the accumulation of phylogenetic data now far outpace comparative morphological and physiological studies, which can be labor-intensive for obtaining data for a few, or even just one, species. While limited, comparative data do exist for some topics and could be analyzed using comparative methods to investigate correlations between physiological features or examine character evolution over the phylogeny. In fact, the authors do make some claims regarding the change or conservation of traits across phylogeny. For example, the authors state that the energy source underlying metamorphic climax varies "interspecifically with little phylogenetic inertia" (p. 110), though this appears to be based on only four species from three families. It seems that the authors intended to use comparative analyses to make use of recent phylogenetic data. However, the only example that I could find of using comparative data in a phylogenetic context is the analysis of standard metabolic rate that appears in the sections on phylogeny and environmental physiology and on comparative methods. The authors might have missed an opportunity by not combining available data from recent phylogenetics research with that from either comparative physiology or the morphotypes that they describe. The text is peppered with comparisons between "aquatic" and "terrestrial" species, though usually with little mention of phylogenetic relationships. By couching these arguments in a phylogenetic context, the authors could have made an even stronger case concerning the environmental correlates of observed physiological diversity.

Perhaps most importantly, this review by Hillman and co-authors underscores that the vast majority of living amphibians still remains to be studied in physiological research. We know little of the physiology of most amphibian larvae, exceedingly little about caecilians, not much about the relationship of physiological

phenotypes with genotype × environment interactions, and without better studies of interspecific variation we will lack the insight into the "hows and whys" underlying physiological variation. With appropriate estimates of the amphibian tree of life in hand, we now need to integrate these with ecological and physiological data to understand "how environmental differences have shaped intra- and interspecific variation in amphibians' physiological performance" (p. 376). A book such as this one is poised to inspire students to do exactly that.

JEFFREY C. BEANE

North Carolina State Museum of Natural Sciences, Research Laboratory
MSC # 1626, Raleigh, North Carolina 27699-1626, USA
e-mail: jeff.beane@ncdenr.gov

This book is the third in a series on amphibians and reptiles of the Southeast published by the University of Georgia Press. It closely follows the format of the two previous volumes on snakes (Gibbons and Dorcas 2005) and turtles (Buhlmann et al. 2008), and covers the same nine-state region (Virginia, Tennessee, the Carolinas, Georgia, Florida, Alabama, Mississippi, and Louisiana) defined as the Southeast in the other volumes. Like the others in this series, it was written with a broad and general readership in mind, but it will also be highly useful to professional herpetologists and seasoned naturalists.

Species accounts are included for all 42 (38 native and four introduced) species known from the region. Each account is divided into sections on "Description," "What do the tadpoles look like?," "Similar species," "Distribution and habitat," "Behavior and activity," "Food and feeding," Description of call," "Reproduction," "Predators and defense," "Conservation," and "Comments." Each also contains several photographs, shaded distribution maps of the species' range within the region as well as its overall range, a sidebar with quick identification tips, and a bar chart with peak calling months indicated by shading. In addition, the book includes a thorough introductory section, a glossary, a table of calling months for all species, a quick-reference table of species found in each state, a list of further reading, indices of scientific and common names, and a closing section on human-anuran interactions. The pages throughout are punctuated with "Did you know?" sidebars featuring interesting facts on frogs and toads. The book carries a strong conservation message throughout, and I have only praise for this conservation-oriented approach.

The more than 300 color photographs range in quality from adequate to excellent. Virtually all serve their purpose of showcasing anuran beauty and diversity, pointing out important identification features, and illustrating intraspecific variation. This last is an especially important feature — too many works allow only a single photograph or illustration of each species covered and fail to adequately cover the often extensive range of variation exhibited by most species. In a few cases, the choices of included photographs could have been improved upon. For example, all the included images of *Hyla squirella* show similarly-colored bright green individuals. As this frog is, color-wise, one of the most variable species in the Southeast, it would have been helpful to have included more images of individuals in gray, brown, and heavily spotted liveries. Several photographs are included more than once. While there is certainly nothing wrong with that *per se*, it may present an illusion that the book has more photos than it actually does, and considering the cost of color printing and the great array of quality anuran photographs available, any such repetition seems unnecessary.

Most of the errors I noticed are ones I would regard as minor. To cite a few examples, on pages 10 and 78 (one of the aforementioned instances of an image being included more than once) a ribbon snake is misidentified as a common garter snake. I also believe the metamorphs identified as green treefrogs at the bottom of page 13 are probably squirrel or possibly pine woods treefrogs. "Brumation" is misspelled in the glossary and "Pine Barrens" is misspelled twice ("Pine Barren" and "Pine barrens") on page 82. The green treefrog account (page 76) states that "no other southeastern treefrog has small, bright orange or gold spots" (in fact, the barking treefrog also frequently has such spots). Page 142 shows "a river frog transforming from a tadpole into an adult" (". . . into a juvenile" would be more accurate). There are a number of errors in the index. For example, the index lists a nonexistent reference to squirrel treefrogs on page 211, and page 207 and 212 feature photographs of a southern toad and a barking treefrog, respectively, but these are not listed in the index. I also found the variable fonts and type sizes, and inconsistent use of italics among the listed page numbers in the index to be slightly confusing. Finally, I am inclined to question the statement (page 44): "Southern and northern cricket frogs occasionally interbreed in areas where

both occur and can produce hybrids that are difficult to identify." While Mount (1975) and Jensen (2005) mentioned possible hybrids between these two species, and Mecham (1964) was able to produce laboratory hybrids, there is apparently scant, if any, solid evidence to support natural hybridization. Mette (2008) and Micancin and Mette (2009) suggested that specimens thought to be hybrids may be merely indicative of the difficulty in identifying these two species morphologically.

I was pleased to see each species account include a brief description of the tadpole, as well as photographs of tadpoles for some species; this is another feature sorely lacking in many anuran field guides. I did feel that some of the tadpole descriptions could have been a bit more accurate, thorough, or clear. While some might argue that tadpoles are often so variable that short verbal descriptions, or even photographs, could potentially be more misleading than useful, I view them as generally helpful, especially for species with particularly distinctive tadpoles (river frog, eastern narrowmouth toad, cricket frogs).

At 7¾" x 10¼", the book's size may hinder its use somewhat as a field guide, but the flexible cover may compensate enough for it to fit into a backpack or otherwise be more easily transported than would a hardback of the same dimensions.

Overall, this volume is an excellent and welcome addition to the series. As the only published work covering exclusively the anurans occurring in the nine-state Southeast region, it will be a valuable addition to the library of anyone interested in the natural history of that region.

TRENTON W. J. GARNER
Institute of Zoology, Zoological Society of London
Regents Park, London NW1 4RY, United Kingdom
e-mail: trent.garner@ioz.ac.uk

Urban Herpetology is a brick. At 40 chapters and 13 case studies, this is not the type of tome one moves casually between office and home. My 20 minute morning walk to work with this bad boy in my rucksack buckled my knees several times and cracked the casing of my lap top. I've successfully blocked ravaging graduate students from entering my office by leaning it against my closed office door. Be forewarned. Also be forewarned that there's useful information in this book. Although I've had some experience with its effects…..the type locality for the Italian agile frog, *Rana latastei*, with which I have worked for several years, is located somewhere in the heart of downtown Milano, where the species is no longer to be found…..I had little familiarity with the specific topic of urban herpetology before agreeing to review this book. I was laboring under the delusion that the study of herps in cities and related areas fell under the old standards of habitat loss and modification, pollution, invasive species and other IUCN-type threats (although even the IUCN has modified their categories: anyone ever heard of transportation and service corridors?). I was pleased to see some familiar words in the section headings and my readings made me realize more clearly how urbanization can bring specific, new and worrying takes on the old IUCN standards. Reading this book has persuaded me that there is a need for me to reconsider how urbanization does and will impact amphibian and reptile populations. I can envision how I may use the information contained within it to some effect, and the chapters I gave short shrift to will be subject to a more thorough reading in the very near future. In the age of narrow focus topical books or superficial undergraduate text books, it is a pleasure to hold a substantial book that covers a fairly broad bit of ground with some depth on a topic that is moving rapidly up the research priority list.

The book opens with a list of contributors, a forward and a preface, followed by an opening overview chapter. This chapter I found exceptionally useful, as it provided me with a tidy historical and geographic overview of urban herpetology. Mitchell and Jung Brown have spent some time collating a valuable list of relevant

references, restricted to English language reference sources, and synthesized their contents neatly. I found their definitions of urban environments most useful, although there is some scope for further refinement. Multiple definitions for exurban are provided, summarized as 1 house per 0.4–16 ha in a matrix that may include native landscapes. This does suggest that Caiapó settlements could be viewed as urbanized, while most would treat the Brazilian forest within which they live as natural.

The rest of the book is broken into sections dealing with various types of habitat alteration (Section I: Direct and Indirect Effects of Habitat Loss and Alteration; Section II: Effects of Roads, Trails and Railroad Tracks; Section IV: Stormwater Ponds, Swimming Pools, Urban Lakes and Golf Courses), pollution (Section III: Chemical and Light Pollution), introduced species (Section V: Introduced Species, Urbanophiles, and Urbanophobes), reviews (Section VI: State, Regional, and Country Reviews), policy (Section VII: Management and Regulations) and outreach (Section VIII: Education and Citizen Involvement). Michael Lannoo provides the afterword. Each section contains up to eight chapters and case studies. Most of the papers specialized on a single or a few species focus on amphibians or chelonians, with a few snake, lizard and crocodilian papers. There are also several papers that attempt to cover both amphibians and reptiles.

I found the papers varied widely in content. Ignoring reviews, quantitative studies ranged from excellent examples of population ecological studies that examined how human-driven habitat change affected population dynamics over time (Chapter 7, Plummer and Mills) to a two-page 'case study' consisting of a collection of anecdotes containing no new empirical data (Case Study 2, Vandeman). In addition, I am unsure that the weight afforded each section was justified. While the number of chapters and case studies in Section I was certainly warranted, why were there only five state, regional, and country reviews? Was it really necessary to have eight chapters and case studies in Section IV, or three chapters outlining the welfare issues of roads? Having said that, I applaud Andrews and Gibbons (Chapter 10) for presenting some rare empirical evidence of possible ecological costs of road mortality to snake populations. As discussed by Andrews, Gibbons and Jochimsen (Chapter 9), most studies of road mortality simply present counts of animals found dead on roads and extrapolating this animal welfare issue to actual population regulation and conservation is fraught with assumptions. While counting dozens or even hundreds of dead reptiles and amphibians on roads is appalling from a welfare point of view, if such a level of slaughter is maintained over time, this suggests that road mortality may not be increasing the likelihood of population extirpation. I encourage other researchers to go and determine if road mortality actually has the ability to regulate populations.

The organization and classification of papers is, on occasion, confusing. Hayes et al.'s study (Chapter 31), arguably one of the best of the book, reviews the ecology of *Rana aurora* in depth and puts it in context of existing legislation, making recommendations as to where legislation fails this species. Even the authors consider it a case study for the species however the paper has been classified as a chapter and put in the section on state, regional and country reviews, even though it is a species review. This chapter is an exception: overall, papers are correctly categorized. The book does have a large number of unreplicated studies that rely on comparisons with previously published data to make conclusions as to the 'health' status of urbanized populations. Not ideal, and any such conclusion must be taken with a grain of salt, even though I do acknowledge the manpower and funding limitations imposed on research groups that dictate how much new data can be collected at any one time. Perhaps this may serve as a call for different research teams studying the same species in urban versus rural versus 'natural' habitats to join forces and develop broader, more comparative studies?

I have three major issues with this book. First, the editors claim that *Urban Herpetology* encapsulates a global perspective, stating their hope that the book will "....set the stage for future research and conservation efforts around the world…." Clearly overblown: Mitchell and Jung Brown cite numerous recent and empirical studies from Africa, Europe, Canada and Australia in their opening chapter, along with some additional studies from Asia and Latin America, yet most chapters and case studies are based on studies of herps in the United State. There is a smattering of data chapters from Europe, Canada and Australia, along with two review articles representing Russia and the West Indies, but these come across as sops when compared to the number of U.S. studies included in the book versus the spectrum of available published literature tabulated and cited in Chapter 1. This bias narrows the insight into urban herpetology afforded readers of the book because the contents do not reflect the distribution of research effort on the topic. As stated by Mitchell and Jung Brown "….much of the available herpetofaunal literature on the impacts of urbanization……is based on work done in Europe. The only serious long-term studies have been conducted (t)here." Further: "A growing body of literature on urban amphibians and reptiles continues to be produced in Australia." The bias extends to the selection of section headings and their contents, to the detriment of herpetologists in other parts of the world. I find it unlikely that researchers in much of Africa, Asia and Latin America will find the section on stormwater ponds, swimming pools, urban lakes and golf courses valuable. Researchers studying how urbanization affects herps in the U.S.A. would certainly benefit from understanding how advanced and long-term urbanization in areas such as Europe, Africa, the Fertile Crescent and some parts of Asia has impacted herps in those regions. Imagine studying the ecology of urbanized herps in Tokyo, the focus of Imperial Japanese power since the shogun of Edo won a civil war in the 16th century and subject to increasing levels of urbanization ever since! Are there any herps to be found in Greater Tokyo? Urban Herpetology doesn't answer this question, but a quick Google hunt returns a study by Kusano and Inoue (2009) on the breeding phenology of three Japanese amphibian species in the suburbs of Tokyo, rather ironically published in the *Journal of Herpetology*. Of course, SSAR is an organization based in the United States, but once claims of a global perspective are made, a lack of attention to it grates.

My second issue is with the complete lack of a genetics perspective. Habitat alteration, fragmentation and pollution, to name a few relevant urbanization processes, are known to influence genetic structure, and there is a wealth of genetic studies on urbanized herps to support this (e.g., Madsen et al. 1996, 1999; Hitchings and Beebee 1997; Andersen et al. 2004; Johansson et al. 2005; Lesbarrères et al. 2006; Ficetola et al. 2007; Noël et al. 2007; see Beebee 2005 for a review of genetics applications that are applica-

ble to studies of urbanized herps). These studies consistently show how habitat fragmentation due to urbanization decrease genetic variability and gene flow among populations, often with associated population-averaged or individual fitness costs. Quantitative genetics have been used to explore amphibian responses to acid stress, providing insight into the potential for a species to adapt in the face of increasing chemical pollution (Merilä et al. 2004). Recent developments in Bayesian population genetics approaches have been successfully used to reveal demographic processes that were not detected using standard field ecology methods (e.g., Jehle et al. 2005). Many of the studies included in Urban Herpetology describe demographic processes that should elevate genetic drift, such as low migration rates, and populations exposed to factors that should impose selection, yet the editors did not think the topic worthy of a single chapter or case study. Why the omission?

My third issue is the decidedly mechanistic perspective evinced throughout the book. Urbanization is set to increase and more species will be forced to exist in human-modified habitat, thus identifying the circumstances that allow species to persist over long time scales is crucial for herpetological conservation. Where is the evolutionary perspective that would facilitate managing urbanized populations? In fact, where is the section on adaptive management, briefly discussed by Hayes et al in Chapter 31? Important questions that can only be addressed using evolutionary concepts are not addressed in *Urban Herpetology*. How can we expect urbanization and climate change to interact and what are the consequences for amphibians and reptiles? Some chapters do take a more dynamic approach to urban herpetology and herpetological conservation, but by and large species and populations are treated as static units and conservation applications as one-off responses to interpretations of current data and trends.

In the end, if you can stump up US $75, the book is worth buying after you determine if the range of topics, taxa, and geographic regions are relevant to your research program. My hope is that this first book on urban herpetology will generate follow-ups, along the lines of Seigel and Collins' snake ecology books or, better yet, Krebs and Davies' series on Behavioral Ecology, that take this decent, but limited, first effort into as yet unexplored aspects of urban herpetology.

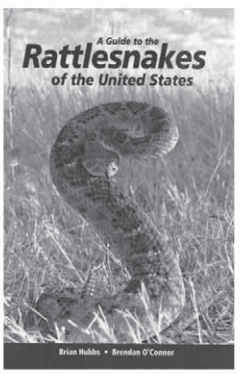
The Herpetological Community

Your many years of dedication to field research, keen eye, perseverance, deep understanding and appreciation of your subjects, and timeless contributions will continue to inspire those of us who study reptiles and amphibians for many, many years to come.

Announcing Two New Publications from Tricolor Books



Common Kingsnakes
A Natural History of *Lampropeltis getula*

Brian Hubbs

The Common Kingsnake ranges from the Pacific to the Atlantic Coasts, and occurs in an impressive array of subspecies and regional variants. In this impressive volume, Hubbs covers all aspects of their natural history and distribution, including conservation status. A separate section provides detailed information on their care in captivity. This book is an invaluable resource for anyone with an interest in reptiles, from the amateur naturalist to hobbyist breeder to professional biologist.

436 pages, 560 photos (majority in color), over 40 range maps, glossy paper, 8½ x 11

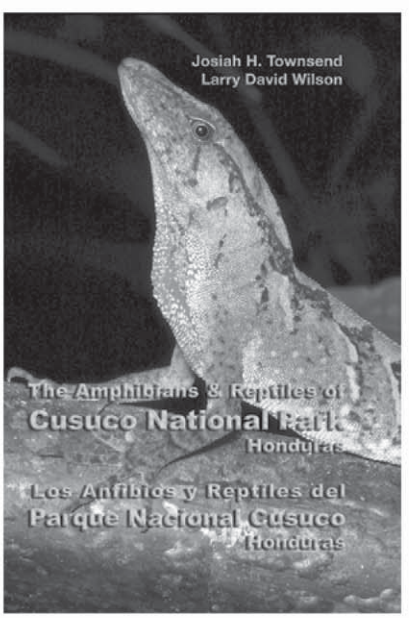
Softcover $60.00 (+ $7 shipping to US and Canada; AZ residents please add $4.86 sales tax) 978-0-9754641-1-3 June 2009

A Guide to the Rattlesnakes of the United States

Brian Hubbs & Brendan O'Connor

This is the first field guide for all U.S. rattlesnakes. Detailed information, including natural history and conservation, for each of the 31 kinds of rattlesnakes occurring in the U.S. presented in a style accessible to all readers.

96 pages, 101 color photos, 31 range maps, glossy paper, 5½ x 8½



Softcover $20.00 (+ $3 shipping to US and Canada; AZ residents please add $1.62 sales tax) 978-0-9754641-2-0 May 2009

Order both books for only $70 + $6 shipping (AZ residents please add $6.08 sales tax)

Also available from Tricolor Books...
Mountain Kings: A Collective Natural History of California, Sonoran, Durango and Queretaro Mountain Kingsnakes

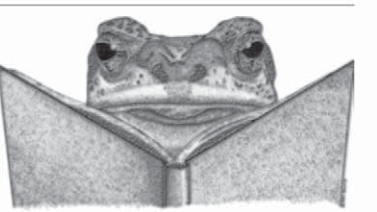
The Amphibians & Reptiles of Cusuco National Park, Honduras
Los Anfibios y Reptiles del Parque Nacional Cusuco, Honduras



Josiah H. Townsend and Larry David Wilson

Cusuco National Park in northeastern Honduras is home to 50 species of amphibians and reptiles, nine of which are endemic to the park. This book, in English and Spanish, is an in-depth guide to the park's herpetofauna.

Specifications: xiv, 322 pages, 6 x 9 inches. Hardcover (ISBN: 978-1-932871-12-8) $44.95 + postage.

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.php>

Reprints and Page Proofs

Reprints of notes or articles published in ***HR*** may be ordered through EZReprints (EzReprint@odysseypress.com), an online reprint odering system. Authors will receive email notification as the issue goes to press. Page proofs are sent electronically to authors of all articles, book reviews, and obituaries, but are not sent for natural history notes or geographic distribution notes. Proofs are sent as pdf files approximately 2–4 weeks prior to publication.

Advertising

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR web page (http://www.ssarherps.org/pages/HRinfo.php).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Central Michigan University, Department of Biology, 217 Brooks Hall, Mt. Pleasant, MI 48859, USA. Periodicals postage paid at Mt. Pleasant, MI 48859 and at additional mailing offices. All rights reserved. No part of this periodical may be reproduced without written permission of the Editor, except that authors and their agents are permitted to reproduce and distribute their own articles and notes. **POSTMASTER:** Send address changes to *Herpetological Review*, Allen Press, Inc., P.O. Box 1897, Lawrence, KS 66044, USA. Regarding missing or damaged issues, please notify *Herpetological Review*, Allen Press, Inc., P.O. Box 1897, Lawrence, KS 66044, USA (tel. 785/843-1234 or e-mail: herps@allenpress.com).

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: http://www.ssarbooks.com/.

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available for purchase from the SSAR Bookstore (http://www.ssarbooks.com/). Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 840		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)		$35
INCOMPLETE SET: NUMBERS	1 – 190	$75
	191 – 410	$85
	411 – 840	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com. Online orders at: http://www.ssarbooks.com/.

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

ANNUAL DUES AND SUBSCRIPTIONS: Annual membership dues for the year 2009 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$70 (Student $35)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$95 (Student $50)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION (BASIC)** $140—includes *JH* and *HR*. **INSTITUTIONAL SUBSCRIPTION (COMPREHENSIVE)** $170—includes *JH, HR*, and *Catalogue*. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ssarherps.org/pages/membership.html.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology,* and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

To join SSAR or to renew your membership, please visit the secure online Allen Press website:

http://timssnet.allenpress.com/ECOMSSAR/timssnet/common/tnt_frontpage.cfm

Future Annual Meetings

2009 — Portland, Oregon, 22–27 July (with ASIH, HL)
2010 — Providence, Rhode Island, 7–12 July (with ASIH, HL)

About Our Cover: *Sceloporus minor*

The spiny lizards of the genus *Sceloporus* range throughout much of the United States south into Central America and number approximately 90 species (Bell et al. 2003. Acta Zoológica Mexicana [n.s.] [90]:103–174). The genus reaches its greatest diversity in central Mexico, with as many as 9 or 10 species co-occurring in many places. They occupy a diversity of habitats and niches, and range in size from the diminutive *Sceloporus parvus* (SVL ~50 mm) to the relatively large *S. serrifer* (≥ 150 mm SVL).

Of particular interest are populations within the *S. jarrovii* complex, a group of closely related species (Wiens et al. 1999. Evolution 53[6]:1884–1897; Wiens and Penkrot 2002. Sysematic Biology 51[1]:69–91; Martínez-Méndez and Méndez-de la Cruz 2007. Zootaxa 1609:53–68), the males of which exhibit high levels of variation in dorsal coloration, presumably the result of sexual selection (Wiens et al., *op. cit.*). Certainly this is true for *S. minor*, a species associated with rocky. mountainous terrain from northeastern Zacatecas, central Nuevo Leon, and western Tamaulipas south though San Luis Potosi to Guanajuato, Querétaro, and Hidalgo. In some locations, this lizard occurs in extremely high densities, and males display a variety of dorsal colors—gray, gold, or red, often with blue highlights on the head, legs, and tail. On some individuals, this blue coloration can be extremely bright, and may cover the entire dorsum.

Our cover features a young adult male *Sceloporus minor* photographed by **Troy Hibbitts** in August 2008 in the Sierra Madre Oriental of central Nuevo Leon, Mexico. Individuals of this population display unusually gaudy colors, with some specimens exhibiting a complete dorsal suffusion of blue. To record this image, Troy used a Nikon D50 and a Sigma 17–70mm lens set at a focal length of 17mm (ISO 800, F22, 1/60th second exposure) with a Nikon SB600 as fill flash. Hibbitts is a high school science teacher in Texas, and often travels to Latin America to photograph herpetofauna.

SSAR BUSINESS

SSAR Grants-in-Herpetology 2009 Annual Report

An award in the amount of US $500 was made to each of the following individuals:

Conservation.—**Rosalinda Palomo-Ramos**, New Mexico State University, "Foraging ecology and nutritional requirements of the Bolson Tortoise (*Gopherus flavomarginatus*) in the northern and southern Chihuahuan Desert."

Field Research.— **Jeanine Refsnider**, Iowa State University, "Can maternal nest-site choice compensate for the effects of global climate change on reptiles with temperature-dependent sex determination? A common-garden experiment using a model species."

Laboratory Research.—**Brittany S. Barker**, University of New Mexico, "Phylogeography of a montane endemic and its widespread congener: *Eleutherodactylus portoricensis* and *E. antillensis* in the Caribbean."

Travel.—**Arley Camargo**, Brigham Young University, "Species boundaries and phylogeny of the *Liolaemus darwinii* species group (Squamata: Liolaemini)."

International.—**Carlos Miguel Del Valle-Useche**, Universidad Nacional de Colombia, "Conservation and management of the Colombian slider turtle (*Trachemys callirostris*) based on mtDNA sequences."

Education.—**Dan Costel**, Lowry Park Zoo, "Amphibian Crisis Education Project."

2009 Grants-in-Herpetology Committee.—Co-chairs: Erik R. Wild and Josh Kapfer. Reviewers: Jeffrey Parmelee, Eli Greenbaum, Rebecca Christoffel, Rich King, Melissa Pilgrim, Jerry Husak, Greg Haenel, Mike Pauers, John Maerz. SSAR congratulates the 2009 GIH recipients and thanks the committee members for their efforts.

SSAR Silent Auction Donations

The SSAR announces the Thirteenth Annual Silent Auction to be held at the 2009 Joint Meeting of Ichthyologists and Herpetologists (JMIH) in Portland, Oregon, July 22–27. In previous years, items for the Silent Auction have been limited to frameable art. However, this year, we are glad to accept any herp-related donations, including, but not limited to, frameable art (photographs, paintings, and line illustrations), books, music, glassware, jewelry, clothing and gift certificates for Portland area services/events during the meeting week. The SSAR Student Travel Committee organizes the Annual Silent Auction to raise money to fund the student travel awards to the JMIH. Your donations help provide opportunities for students to attend and present their research. If you are interested in donating an item or two (tax deductible for U.S. residents), please contact Matthew D. Venesky (mvenesky@memphis.edu) for more information.

MEETINGS

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (HerpReview@gmail.com) well in advance of the event.

18–20 July 2009— 5th Meeting of the Snake Ecology Group, Donnelly, Idaho, USA. Registration and information: http://www.projectorianne.org/SEG_5.html.

22–27 July 2009— 52nd Annual Meeting, Society for the Study of Amphibians and Reptiles; 89th Annual Meeting, American Society of Ichthyologists and Herpetologists; 67th Annual Meeting, The Herpetologists' League. Portland, Oregon, USA. Information: http://www.dce.ksu.edu/jointmeeting/.

5–8 August 2009— 7th Annual Turtle Survival Alliance Symposium on Chelonian Conservation and Biology, St. Louis, Missouri, USA. Information: http://www.turtlesurvival.org.

12–17 September 2009— Association of Zoos and Aquariums Annual Conference, Portland, Oregon. Information: http://www.aza.org/AnnualConference/index.html.

2–4 October 2009— Symposium on *Anolis* Biology, Harvard University, Cambridge, Massachusetts, USA. Information: http://anolis.oeb.harvard.edu.

16–17 October 2009— Texas Herpetological Society Fall Symposium, Texas A&M University, College Station, Texas, USA. Information: www.kingsnake.com/ths.

17–19 October 2009— Gaffney Chelonian Fossil Symposium, Drumheller, Alberta, Canada. Information: http://www.tyrrellmuseum.com/events/turtlesymp09.php

CURRENT RESEARCH

The purpose of Current Research is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, Joshua Hale or Ben Lowe; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can be found at: http://www.herplit.com/contents.

Different Male Color Morphs Display Alternate Mating Strategies in a Lizard

Sexual selection may operate both pre- and post-mating and may involve a number of different mechanisms. Typically, males of the same species demonstrate similar reproductive strategies; however this is not always the case. The Australian Painted Dragon, *Ctenophorus pictus*, consists of three male head color morphs: red, yellow, and orange. In a previous study, it was shown that red males outcompete yellow males in staged encounters for females. Furthermore, red males emerge and establish territories in the wild earlier than yellow males. In this study, the authors measured relative testes size of the color morphs and conducted a number of mating experiments in which females were allowed additional matings with males of different colors, both within the same and across different ovarian cycles. Yellow males had larger testes relative to body size than red males, and were observed to copulate for a shorter time. Microsatellite loci were used to determine paternity, with the authors demonstrating that females are able to store sperm, with males able to sire offspring in an ovarian cycle subsequent to the mating event. Furthermore, these analyses revealed that yellow males sired three times more offspring per copulation than red males (evidence for numerical sperm competition). The authors conclude that the color morphs may be associated with different reproductive tactics, with the yellow morphs able to adopt a "sneaker" strategy due to their larger testis size.

A Review of the Success of Translocations in Amphibians and Reptiles

Translocations are widely used to aid species conservation; however, their usefulness is still keenly debated. In this study, the authors have reviewed the results of amphibian and reptile translocation studies published between 1991 and 2006. In all, 85 translocation projects were examined, 38 of which involved amphibians and 47 involved reptiles. The success rate of translocations was independent of taxonomic class (amphibian or reptile) and was twice that observed pre-1991. The success of amphibian translocations was tightly linked with the number of individuals involved. Translocations in which greater than 1000 individuals were released were more successful than smaller introductions. Translocations most often failed due to poor release site habitat and migration of introduced individuals. Although the authors suggest that the increased success of recent introductions is encouraging, more work is needed, especially research into stress responses of released animals.

Living on Rocks Determines Patterns of Morphological and Performance Evolution in Lizards

Worldwide, lizards occupy a wide array of habitats, yet there remain few cases where habitat use, morphology, and performance,

are clearly related. The best known cases include an increase in limb length in response to increased perch diameter in arboreal anoles. Rocky habitats impose strong natural selection on specific morphological characteristics, which differ markedly from those imposed on terrestrial and arboreal species. Using comparative phylogenetic methods, the authors examined the habitat use, morphology, and performance (sprinting, climbing, clinging and jumping) of 23 populations of skinks representing 19 species from tropical Australia. These populations occupy habitats with considerable variation in rock availability. This study revealed that the occupation of rock-dominated habitats was correlated with the evolution of increased limb length, relative to species from forest habitats that predominantly occupied leaf litter. Moreover, increased limb length directly affected performance, with species from rocky habitats having greater sprinting, climbing, and clinging ability than their relatives from less rocky habitats. The authors conclude that the degree of rock use is correlated with both morphological and performance evolution in this group of tropical lizards.

Phylogenetic Placement of Lacertidae in the Squamate Mitochondrial Tree

Representatives of the lizard family Lacertidae have proven to be useful model organisms in a number of studies; however the phylogenetic position of Lacertidae within Squamata has remained controversial. In this study, the authors completed sequencing of the entire mitochondrial genome for three lacertid lizard species (*Podarcis siculus*, *Podarcis muralis* and *Phoenicolacerta kulzeri*), and together with 16 previously published complete mtDNA genomes, conducted phylogenetic analyses (Maximum Parsimony [MP], Bayesian Inference [BI]) in an attempt to reconstruct the mtDNA relationships within Squamata. In concordance with results from previous analyses of molecular data, the results of these analyses confirmed Amphisbaenia as the sister taxon of Lacertidae. Interestingly, in contrast to previous studies (based both on morphological and molecular data), a well supported clade consisting of Gekkota and Lacertidae/Amphisbaenia was recovered in one of the analyses (BI); the MP analysis placed Gekkota as sister to remaining sampled squamates, in line with other recent studies. Finally, analysis of the mtDNA genes commonly used for phylogenetic analyses within Lacertidae revealed extremely high levels of divergence, suggesting an ancient divergence within *Podarcis*.

Influence of Landscape on Population Genetic Structure of a Salamander

In this study, the authors have examined the population genetic structure of the spotted salamander, *Ambystoma maculatum*, in northeastern Ohio, a landscape fragmented by natural features such as the Cuyahoga River, but also human-induced alterations such as roads, urbanization and agricultural development. The authors used 8 polymorphic microsatellite loci to investigate population genetic structure of 407 individuals across 17 populations. In contrast with the findings in a number of other taxa, no effect of geographical distance or landscape barriers on dispersal was observed. The authors suggest that this pattern may have been observed because insufficient time has passed since anthropogenic fragmentation for the detection of a change in population structure. Alternatively, dispersal interruptions caused by fragmentations could be compensated for by more effective dispersal via alternative routes. The authors suggest that the high level of connectivity between ponds, despite apparent barriers and hostile inter-pond landscape, could be related to dispersal pathways which run along the network of riparian corridors linked with the Cuyahoga River.

Purrenhage, J. L., P. H. Niewiarowski, and F. B.-G. Moore. 2009. Population structure of spotted salamanders (*Ambystoma maculatum*) in a fragmented landscape. Molecular Ecology 18:235–247.

Parental Care in a Tropical Skink in the Face of Different Predation Risks

Reptiles rarely demonstrate parental care, and if they do, it is usually restricted to egg-guarding. Despite egg-guarding behavior representing an extremely primitive form of parental care, the influence of predators on this behavior remains relatively unknown. In this study, the authors have investigated parental care in a tropical skink from Taitung County, Taiwan, *Mabuya longicaudata*, in the face of different predation risks. The authors manipulated encounters between different predators and female skinks in naturally occurring nests shortly following oviposition. When presented with the egg-predating snake *Oligodon formosanus*, skinks reacted aggressively, attacking the predator on each occasion and increasing the amount of time egg-guarding. In contrast, when presented with non egg-predating sympatric skinks, *Sphenomorphus incognitos* and *Japalura swinhonis*, female *M. longicaudata* skinks did not behave aggressively or change their egg-guarding behavior. When presented with the skink-predating snake *Elaphe carinata*, female skinks escaped and did not return to the original nest. The authors suggest that egg-guarding in this species reflects precise and complex behaviors adapted to specific reptile predators.

Giant Prehistoric Snake Used to Estimate Past Climate

In this study, researchers describe a prehistoric boid snake, *Titanoboa cerrejonensis*, from northeastern Colombia, which is estimated to be about 58–60 million years old. Fossilized vertebrae found in the Cerrejón Coal Mine indicate that *Titanoboa* is the largest snake ever discovered, measuring 13 m in length and weighing 1135 kg. The extremely large size of this prehistoric snake provides interesting clues as to the environmental conditions of the time period, and has allowed the authors to use *Titanoboa* to reconstruct the climate of the neotropics in the Paleocene. Based on the size of *Titanoboa* in comparison to *Eunectes murinus*, the largest extant snake in the neotropics, the authors estimated that *Titanoboa* would require a mean minimum annual temperature of 30–34ºC to survive. This estimation is consistent with independent climate models, which predict hot Paleocene temperatures and high atmospheric concentrations of CO_2. Similarities between the deposits in which *Titanoboa* were found and the habitat of the extant *Eunectes* and inferences about prey taxa, including crocodyliforms, suggest *Titanoboa* had an ecology similar to modern anacondas.

A Novel Species of Land Iguana from the Galápagos

On Charles Darwin's visit to the Galápagos, he encountered both marine (*Amblyrhynchus*) and yellow land (*Conolophus*) iguanas, but not the rare, pink land iguana referred to as "rosada." Despite the considerable scientific focus on the Galápagos subsequent to Darwin's expedition, the rosada form, which occurs only on an Isla Isabella volcano named Volcan Wolf, was first observed only in 1986. In this study, the authors used mtDNA and microsatellite genotyping to investigate the taxonomic status of the rosada form. The rosada iguanas were found to form a well supported clade sister to a clade containing all remaining *Conolophus* (comprising two named species and the natural inhabitants of six islands including Isla Isabella, where they occur in sympatry with members of the rosada clade). Interestingly, this result places the timing of divergence of the rosada lineage to a point before all of the present day islands had formed. The rosada is also morphologically distinct; in addition to their color, they can be distinguished by flat dorsal head scales and a characteristic nuchal crest. Furthermore, differences are present in head-bobbing behavior, which is thought to be important in territory defense and courtship. Finally, the authors propose that their analysis suggests that the rosada form should be elevated to full-species status and a conservation program should be initiated in order to protect it from extinction.

Impact of Predation Risk on Larval and Post-Metamorphic Phenotypes in a Frog

Phenotypic responses to environmental pressures may constrain the future phenotype, reducing the fitness of the individual at later life-stages. In this study, the authors investigated the phenotypic response of tadpoles of the Common Frog, *Rana temporaria*, to perceived predation risk and how this impacted the post-metamorphic phenotype. Egg masses collected near Glasgow, Scotland were reared through to metamorphosis in the laboratory, either in the presence or absence of a predator, larvae of the odonate *Aeshna juncea*. Predators were housed with the tadpoles, but were kept separate in a cage, ensuring that no actual predation could occur. Tadpoles raised in the presence of the predator developed deeper tail fins and muscles, and swam further than tadpoles reared with no predator. At metamorphosis, tadpoles reared under predator and control treatments did not differ morphologically. However, 12 weeks post-metamorphosis, frogs that developed in the predator treatment had narrower femurs and swam more slowly and less far than control frogs. The authors suggest that this trade-off indicates that phenotypic adaptations made early in development can have consequences in later life-stages.

Stamper, C. E., J. R. Downie, D. J. Stevens, and P. Monaghan. 2009. The effects of perceived predation risk on pre- and post-metamorphic phenotypes in the common frog. Journal of Zoology 277:205–213.

Low MHC Variation in Long Surviving Populations of Newts

Major histocompatibility complex (MHC) genes are an important component of immune response, and a reduction in polymorphism is predicted to limit a population's ability to counter novel disease threats. Understanding amphibian responses to pathogens is particularly important in the face of the global amphibian declines. In this study, the authors investigated MHC class II variation in a number of populations of the Great Crested Newt, *Triturus cristatus*. Refugial populations from Romania were sampled, as well as postglacial expansion populations from Germany, Poland, and the UK. Refugial populations demonstrated extremely high levels of adaptive variation with 24 expressed alleles. In contrast, areas colonized during the postglacial expansion possessed very low levels of variation, with only two expressed alleles. Despite the low level of MHC variation in these areas, these populations have survived 10,000 years, suggesting that low levels of MHC variation may not be a critical problem for long-term population persistence in Great Crested Newts.

Fernando Mendoza holding a *Crotalus aquilus*, 16 July 2005, at El Calicanto in the Sierra de Pachuca, Hidalgo, México. Photo by Alan Kardon.

On 14 September 2008, Fernando Mendoza Quijano was tragically killed, at the age of 51, in an automobile accident northwest of Gómez Palacio while on his way to Casas Grandes, Chihuahua, to obtain a collection of books from an American collaborator for his students in Hidalgo, México. Also dying instantly in the crash, caused by an oncoming pickup truck swerving into their lane of travel, was his wife and collaborator Giselda Quijano Manilla. He is survived by seven children: Fernando Ricardo Mendoza Paz, Claudio Alberto Mendoza Paz, Orlando Mendoza Paz, Mónica Mendoza Cabrera, Cecilia Mendoza Cabrera, Daniela Mendoza Cabrera, and Julio Mendoza Mehenes. An eighth child, Mario Alejandro Mendoza Paz, died in 2006.

Fernando Mendoza Quijano was born on 3 April 1957, in Mexico City to Napoleón Mendoza Hernández and Esperanza Quijano Simón and attended primary school at Instituto Liceo de México for six year, where he was recognized for excellence, at the top of his class. He then attended high school at the Escuela Secundaria Técnica No. 3 "Héroes de Chapultepec," followed by studies at the national preparatory school, Miguel E. Schultz No. 8 (1973–1975). His professional training as a biologist was at the Escuela Nacional de Estudios Profesionales-Iztacala at the Universidad Nacional Autónoma de México (UNAM) in Tlalnepantla. He completed his degree in 1991 with a thesis titled "Estudio herpetofaunístico en el transeco Zacualtipán-Zoquizoquipan-San Juan Mextitlán, Hidalgo" followed by a master's degree in the Facultad de Ciencias of UNAM in 1995, titled "Variación genética y distribución geográfica de las lagartijas del grupo *variabilis* del género *Sceloporus* (Squamata: Phrynosomatidae)."

Fernando Mendoza, in a characteristic pose, recording his precise field notes, 24 July 2005, Valle de los Fantasmas, San Luís Potosí, México. Photo by Robert W. Hansen.

Fernando found a calling for his many inspirational talents in teaching, first at the Escuela de Biologia at the Benemérita Universidad Autónoma de Puebla, Puebla, México (1996–1997), and then (1997–2008) as Profesor Asociado "C", Instituto Technológico Agropecuario No. 6, Huejutla de los Reyes, Hidalgo, México. He maintained a close relationship with herpetologists at UNAM (as Investigador Asociado, Colección Nacional de Anfibios y Reptiles), and served on many thesis committees at UNAM (including as thesis director) as well as at Huejutla (nearly 40 in all). Although mostly herpetological, Fernando facilitated the interests of his students in other areas of vertebrate biology, ethnobiology, and conservation. But his teaching talents

were not confined to the classroom as he radiated his knowledge of and enthusiasm for Mexican herpetology to all those around him, in the field, at Mexican and U.S. herpetological conferences, in symposia, and in special courses and seminars that he attended or arranged—at least 75 (1984–2005).

Fernando has been well known to herpetologists throughout Mexico and the United States for over two decades through his broad herpetological interests, publications, and personal contacts and collaborations he made with colleagues at meetings and in the field in both countries (as well as in Costa Rica). He read the herpetological literature widely and carefully, and always encouraged his students in their efforts at learning English. Fernando was dedicated to the importance of collections and was an active member of the Museo de Zoología "Alfonso L. Herrera" at UNAM and the Museo de Biodiversidad del Mundo Maya at the Universidad Autónoma de Campeche. He played important roles in the Sociedad Herpetológica Mexicana. He wrote widely on species distributions and regional faunas, having published over 90 papers, scientific notes, and book chapters in 18 journals and 6 books, and having left many manuscripts in press, submitted, and in preparation. He was keenly aware of and deeply concerned about the impacts of ecological changes, due to human activities throughout Mexico, on reptiles and amphibians as well as on the natural world. Fernando was always interested in taxonomic questions and in learning to utilize the best modern methods available to him for resolving them. The number of his collaborators from Mexico and the United States listed in his curriculum vitae on herpetological projects, well over a hundred, is truly impressive, and it speaks deeply to Fernando's ability to engage others with his passion for reptiles and amphibians.

Shortly after his death Fernando was remembered on 7 October 2008 at the 10th Annual Meeting of the Sociedad Herpetologica de México in Pachuca, Hidalgo. In a slide tribute ("One Man Made a Difference: Tribute to Fernando Mendoza Quijano," arranged by Robert W. Bryson, Jr. and David Lazcano), many friends and associates of Fernando shared their thoughts, a few of which we share here: "I have known Fernando for six years. Never have I met a more selfless, passionate, and giving person…. He always retained a positive outlook on life despite a life full of hardships, and he served as an inspiration for Mexicans and non-Mexicans alike. His friendship was one of the most rewarding and fulfilling experiences that I have ever had" (Bryson); "Fernando fue sin duda uno de los herpetologos más notables que he conocido. Para mí sobresalen entre sus cualidades su gran capacidad, habilidad y tesón para el trabajo de campo… que nunca dejó de trabajar por la herpetologia a pesar de no estar en las mejores circunstancias para ello; sin duda, hizo mucho más con pocos recursos que otros con mayor recursos …. Siempre estuvo dispuesto a ayudar y a enseñar a otros y fue un hombre sencillo y generoso." (Adrián Nieto Montes de Oca); "Mexico has lost one of its best herpetologists, and I have lost a dear friend and valued colleague." (Robert W. Hansen); "Esa combinación de poseer un olfato previlegiado para encontrar anfibios y reptiles en el campo, tener la resistencia y el empuje para sobreponerse a la adversidad y al mismo tiempo ser optimista y entregado es la que te hace única Fer…." (Georgina Santos); "I can remember Fernando from … my lab…. He worked long hours, and was grateful … he was always in a good mood … a delight to be around … and he genuinely enjoyed the cultural diversity of our group … yet managed to tolerate my errors (in Spanish) with the right mix of humor and politeness." (Jack Sites).

Mexican herpetology has lost a great native contributor and a unique person of inspirational ability. He will be missed in the classroom, laboratory, and field by his students and by innumerable herpetologists who have collaborated on studies with him and whose lives have been moved by his energy, perseverance, charm, and dedication to high ideals.

Acknowledgments.—For assistance in compiling information about Fernando's life we thank Fernando Ricardo Mendoza Paz and Robert W. Bryson, Jr.

Updating the Bookshelves Part IV: Important Herpetological Books Appearing During the Last Two Decades

CHELONIANS — CROCODILIANS — AMPHIBIANS
CAPTIVE & MEDICAL MANAGEMENT— ZOO HISTORY

"What shall I do with all my books?" was the question; and the answer, "Read them," sobered the questioner. "But if you cannot read them, at any rate handle them and, as it were, fondle them. Peer into them. Let them fall open where they will. Read on from the first sentence that arrests the eye. Then turn to another. Make a voyage of discovery, taking soundings of uncharted seas. Set them back on their shelves with your own hands. Arrange them on your own plan, so that if you do not know what is in them, you at least know where they are. If they cannot be your friends, let them at any rate be your acquaintances. If they cannot enter the circle of your life, do not deny them at least a nod of recognition."

—*Thoughts and Adventures*, Winston S. Churchill, 1932

CONCLUDING REMARKS

I hope that, after reading this series, zoo and aquarium workers will have been convinced that a personal reference library is an essential tool for learning about the animals entrusted to their care. Also, through the illustrations utilizing spectacular art found in earlier publications, readers will note their connection to important herpetological books and papers of the past twenty or so years. In my opinion, some of this herpetological artwork compares favorably with the finest works hanging in our art museums. Stunningly beautiful and arresting lithographs such as those created by Sowerby and Lear, as well as George H. Ford, Auguste Sonrel, P. J. Smit, Robert Mintern, James Green, C. Berjeau, and John Green during the 19th century, disappeared as the newer and cheaper method of photo-engraving became the technology of choice in the 20th century. Today, even with the advent of digital cameras and computer-enhanced images, the inspiring work of these talented craftsmen can not be matched.

When I talk with some of my younger colleagues, they ask why it is necessary to build a library at all when the internet is available to search for information at great speed and at much lower cost. In fact, a few have accused me of being out of touch with mainstream technology. Many years ago, I asked the late Roger Conant about the advent of computers and how our profession would change. He became agitated and told me that many of the current group of young herpetologists were spoiled by mostly depending on this new technology; in fact, he called them "whiners" when they complained that they occasionally had to do research the "old way" in a library without access to a computer. When Conant began writing his classic *Agkistrodon* monograph with Howard K. Gloyd over 60 years earlier, there were no word-processing programs with spell-check and thesaurus, no bibliographic programs to download references, no statistical or spreadsheet software, and no scanners or copiers to duplicate literature. Each reference was either examined in a library, provided by colleagues, borrowed, or purchased. All requests for information from colleagues and early drafts were typed on a manual typewriter. Every citation with notations was initially hand-written on an index card, then sorted and collated.

In my defense of actual books, I can say that there is something therapeutic, uplifting, and often unexpectedly rewarding about paging through a work written long ago, especially when remembering that authors like Gloyd and Conant had to overcome formidable odds to finish their magnum opus. They examined the phylogeny and zoogeography of the *Agkistrodon* (sensu lato) complex the "old-fashioned way" and explained their approach, "There are no cladistics, no cladograms, no variances, and no divergence events, or any of the other newer approaches and terminology currently in use by phylogenetic systematists." Supercomputers and the new analytical software to drive them were not available to Gloyd and Conant but their conclusions remain robust nonetheless. In defense of libraries, I can add that browsing the stacks often turns up something of value. It must be said here that I do not dislike computers; rather my argument is that books are important too and should not be viewed as unnecessary relics from the past. Although there is a trend to digitize books and make them accessible to a wider audience via the internet, I do not enjoy reading a book from a computer screen. The defense rests!

As our natural world shrinks around us, the content of herpetological books has changed dramatically. Virtually every new title addresses conservation and some accounts are pretty alarming. Three recent examples really caught my attention. The first is *The Amphibians & Reptiles of Cusuco National Park Honduras / Los Anfibios y Reptiles del Parque Nacional Cusuco Honduras,* by Josiah H. Townsend and Larry David Wilson. A chapter is devoted to the subject including a table summarizing conservation assessment criteria.

The second—*The Ecology and Behavior of Amphibians*, by Kentwood D. Wells—devotes an entire chapter, over 70 pages, to the conservation status of amphibians and the news is not good.

The last one—Michael Lannoo's *Malformed Frogs: The Collapse of Aquatic Ecosystems*—is devastating.

Why zoo biologists must publish their observations: Permit me to use one example of how an old text can be more correct than would have been expected. True chameleons fascinate zoo patrons—elaborate ornamentation and rapid color changes, independently rotating eye turrets, zygodactyl feet, extensible prey-catching tongues, and prehensile tails. When I started in the zoo business more years ago than I care to remember, many chameleon species often lived only a few years in captivity. We read all of the literature available and tried a number of different techniques to keep them but only a precious few (Veiled, Panther and Jackson's Chameleons) did well for even a short time.

In 1925, Major Stanley Smyth Flower explained it this way, "As far as the evidence goes, Chameleons appear to be the only short-lived Reptiles, not attaining to even five years. Lizards present varying lengths of life not correlated with their bodily size." Flower found that chameleons rarely lived one year in captivity and in his survey of 55 years, only 15 chameleons out of nearly 770 survived over one year, except the South African Dwarf Chameleon (*Bradypodion pumilum*) which has live young. We read Flower and tried to improve upon the statistics he compiled through the early part of the 20th century. Many of us thought that the failure to thrive was due to our improper husbandry practices and, in fact, zoos have improved their techniques and kept chameleons for longer periods. As field studies trickled in, we read them and eagerly applied the information, and subsequently we published our results (e.g., Ferguson et al. 2004; Murphy 2005).

A new challenge is the recent study by Karsten and associates which explains why some imported animals could probably never have been successfully kept in captivity for extended periods. They found that Labord's Chameleon (*Furcifer labordi*), from arid southwestern Madagascar, is an "annual" lizard living mostly as an egg for about nine months and then only four or five months outside the egg. These lizards reach sexual maturity in two months. This may mean that the brief life span of chameleons in captivity might, for some species, actually represent the natural adult life span. So questions are asked and suggestions given by the authors in their abstract: "Consequently, a new appraisal may be warranted concerning the viability of chameleon breeding programs, which could have special significance for species of conservation concern. Additionally, because *F. labordi* is closely related to other perennial species, this chameleon group may prove also to be especially well suited for comparative studies that focus on life history evolution and the ecological, genetic, and/or hormonal determinants of aging, longevity, and senescence."

As we just learned about Labord's Chameleon, Flower's statement about chameleons being short-lived reptiles written over 80 years ago was prophetic.

Pinou et al. (2009) outlined a first-grade scientific education program that included live amphibian larvae collected from the wild, maintained and studied in the classroom, and then released into their natal pond. The reality of emerging infectious diseases as a primary threat to amphibian populations prompted us to consider carefully some recommendations made by those authors, and also the general notion of reducing disease risks associated with keeping living amphibians in K–12 classrooms—although the same concerns apply to living amphibians in all *ex-situ* situations (see Pessier 2008; Zippel et al. 2006). The sad reality is that the world is no longer a simple place and seemingly innocent acts like catching tadpoles and releasing them later are now much more complex, with regard to conservation imperatives. In general, we applaud the schoolchildren's program outlined by Pinou et al. (2009), as it appears to be an engaging exercise that brings together qualitative

1 – SSAR President-Elect; 2 – AArk Training Officer; 3 – Co-Chair, SSAR Conservation Committee; 4 – AArk Program Director; 5 – Chair, SSAR Herpetology Education Committee; 6 – SSAR Secretary; 7 – SSAR President.

data, the scientific method, and a wonderful element of amphibian natural history. However, a specific recommendation by them raised some initial concern, and led us to engage in some (hopefully) fruitful discussions related to amphibians in classrooms and the potential for spread of diseases. Pinou et al. (2009:33) suggest:

> *"Schools that are interested in participating in similar activities can contact the Herpetologists Education Committee of the Society for the Study of Amphibians and Reptiles (SSAR) at www.ssarherps.org. Ask for a partnering herpetologist that can provide eggs of regional species of amphibians that can be released back into their native habitat once hatched—preventing the disruption of the natural biodiversity."*

We first learned of the publication when, in fact, a number of teachers from around the US began contacting various SSAR officers, looking for leads to "partnering herpetologists." The officers were initially mystified as to the sudden flurry of similar requests, but a bit of investigating revealed the primary inspiration to be from Pinou et al. (2009). We read it with great interest and all quickly agreed that the authors have outlined an insightful and engaging educational activity. The only problem is the line "*….amphibians that can be released back into their native habitat….*" Emerging infectious diseases (e.g., amphibian chytrid fungus and ranaviruses) are now acknowledged as a leading cause of amphibian declines and extinctions (Daszak et al. 2003; Skerratt et al. 2007) and there is increasing recognition that important amphibian pathogens have been disseminated to new locations by anthropogenic means (Jancovich et al. 2005; Picco and Collins 2008; Weldon et al. 2004). As a result, biosecurity becomes an essential consideration as amphibians are being moved between locations, be they any combination of natural habitats and/or captive facilities. The model proposed by Pinou et al. (2009) raises a real potential risk of transferring non-native pathogens back into the natal pond of the amphibians included in the classroom exercise.

It was of primary importance to us not to simply squelch this classroom exercise for reasons of risk avoidance. To us, this exercise is a great example of the spirit of encouraging a collective public conscience of "bioliteracy" outlined so eloquently by Ehrlich and Pringle (2008:11584):

> *"The earlier in the developmental process comes exposure to nature, the better the odds of inspiring devotion to biodiversity and its conservation. It is a rare conservationist who did not encounter nature as a child. Every one of us can go to elementary schools to show pictures of animals and plants and tell funny stories about ecology. The teachers will be happy to have us. More ambitious people might think about how to finance and institutionalize school field trips to natural areas."*

We put authors Pinou, Flanigan, and Drucker (2009) in this latter "ambitious" category, as their program brings salamanders to first-graders, and wraps it all in a solid framework of quantified science. So, how can we encourage programs like this without adding to the already horrendous problem of pathogens and amphibian survival in the wild? We believe that one simple precaution may solve the problem:

> Proceed with the program of Pinou et al. (2009) verbatim, but with the important caveat that absolutely *no other live amphibians are also maintained in the classroom, or that the amphibians cannot come into contact with any other materials shared with other amphibians (e.g., re-used aquaria that have not been sterilized), or that at the time any amphibians are brought into the classroom, they should be maintained in isolation from all other aquatic organisms and their potential pathogens. Setting up the specimens in new or sterilized enclosures will insure this*. This is the simplest, surest, way to eliminate the risk of introducing foreign pathogens back into the pond with those newly hatched amphibians.

We make this simple, but stark, recommendation in full realization that it will limit the diversity of amphibian-related natural experiences that may be presented in the classroom. In other words, we understand that any teacher receptive to the program of Pinou et al. (2009) is likely to be the same teacher who also has a tank full of metamorphosing leopard frog tadpoles, some fire-bellied toads, or perhaps a poison dart frog or two in the same classroom. We certainly experienced (and appreciated) like-minded teachers in our school days—but, sadly, the world has changed and the specter of emerging infectious diseases as a real conservation threat to wildlife no longer makes such activities acceptable. The seriousness of the threat of the amphibian chytrid fungus was made clear by its recent classification as a 'notifiable' disease by the World Organisation for Animal Health (OIE); the full text of the listing is available at http://www.oie.int/eng/normes/fcode/en_chapitre_2.4.1.htm#rubrique_batrachochytrium_dendrobatidis). This means member countries will have to declare annually the status of these diseases in their country and what they are doing to control them.

We also add the reminder that activities such as those described by Pinou et al. (2009) are likely to require collection permits from the appropriate governmental agency. Additionally, if school groups will be moving among field sites, the stringent sanitation protocols of Speare (2001) should be followed. That document is available online (http://www.jcu.edu.au/school/phtm/PHTM/frogs/adrecommendations.htm). Enclosures, gravel, nets, and other items that come in contact with amphibians or their water in the classroom must be disinfected between usages. We recommend a solution of household bleach (usually a 5–6% solution of sodium hypochlorite) that can be made using one part bleach to 3 parts water; a minimum contact time of one minute is necessary.

A related concern about amphibians in the classroom involves animals that are readily available in pet stores, with *Bombina* (fire-bellied toads), *Hymenochirus* (African dwarf frogs), *Litoria* (Australiasian treefrogs), and *Xenopus* (African clawed frogs) seeming to be especially common among the larger retail chains. Additionally, numerous ready-made kits are available so that families and classrooms can watch together the marvel of amphibian metamorphosis. Some retailers and online outlets provide literature advising against release of the tadpole or froglet, some do not. Regardless of the literature accompanying the purchased amphibian, we reiterate here that:

> No amphibian purchased or received from any commercial or informal (e.g., a neighbor) source may be released into the wild. This recommendation applies whether the species is technically "native" to the region of release, or not.

Families or teachers considering the purchase of commercially available amphibian adults or larvae must realize that they are embarking on a commitment for the natural life of that amphibian. We found one online testimonial for a commercial tadpole kit where the family raised the "Bullfrog" for 33 years; this is longer than the careers of some teachers. We recommend the useful pamphlet produced by Partners in Amphibian and Reptile Conservation (PARC) entitled "Don't Turn it Loose" as a guide. It is available on the web (http://www.parcplace.org/DontTurn.pdf). Alternatively,

euthanasia by a licensed veterinarian should be considered. We also note that some amphibian species are small and relatively simple to maintain in good health, but that others—e.g., American Bullfrog (*Lithobates catesbeianus*)—are large and decidedly not so simple to maintain. It is important to note that some diseased amphibians may appear to be completely healthy, showing no signs of illness whatsoever. We pose the scenario that watching chicks hatch from commercially available fertile eggs would also be a wonderful classroom experience, but how many teachers would go on to release those chickens into nearby fields, and how many poultry farmers would accept them (being of unknown genetic lines and veterinary history) into their operations? We present this, at the risk of overstatement, because we have all met teachers, parents, and students of all ages who have released the amphibians from their in-home or classroom experiences into the "pond down the road." They did so with good intentions, but the practice cannot continue and is, in fact, illegal in some US states. As we endeavor to be as supportive as possible of introducing children to amphibians, especially via a strong science curriculum, we suggest the following well-executed resources for teachers to consider bringing into their classrooms:

- *The Amphibian Project* http://www.helpafrog.org/toolkit.htm
- *Amphibians*. 35 min. (by EyeWitness Videos; SKU WW73872M27) Describes amphibian life cycle and anatomy; behaviors and adaptations; and amphibian characteristics. Grades 5-12
- *Caterpillar and the Polliwog* (by Jack Kent ISBN 0-671-66281-3). Book and video that describe metamorphosis of caterpillars and frogs. Grades K-3
- *Tale of a Tadpole* (Eyewitness Level I by Karen Wallace ISBN 0-7894-3437-7). Follows the life of a frog with simple, yet excellent photographs. Grades Pre-2

In closing, as we learn more about the devastating effects that emerging infectious diseases are having on amphibians globally (Daszak et al. 2003; Stuart et al. 2004), we are realizing that various commercial activities by humans are increasingly spotlighted as the culprit in spreading the disease. We know better now, and we hope our simple recommendations will allow innovative programs like that of Pinou et al. (2009) to continue to bring the wonder of amphibians to the classroom, and to do so without risking the very same amphibians we seek to admire.

Prior to the discovery and widespread recognition that pathogens such as *Batrachochytrium dendrobatidis* (*Bd*) and ranaviruses can lead to the decline and even extinction of amphibian populations around the world, few herpetologists used gloves when handling amphibians. Disposable gloves, along with disinfection protocols (Webb et al. 2007), quarantine (Young et al. 2007), and reports by Daszak et al. (2001) and Lynch (2001) have since become an important tool in our arsenal for preventing the spread of pathogens between individuals and among populations or habitats.

Cashins et al. (2008) recently reported that latex, vinyl, and nitrile gloves can be lethal to tadpoles of several species (*Litoria genimaculata*, *L. nannotis*, and *Bufo marinus*), even after short-term exposures during routine handling. Two previous studies had also found that latex and nitrile gloves (or water in which gloves had been soaked) could be lethal to *Xenopus laevis* and *Rana temporaria* tadpoles (Sobotka and Rahwan 1994, Gutleb et al. 2001). In an unrelated study aimed at developing hygiene protocols to prevent the spread of *Bd* among animals, Mendez et al. (2008) reported that bare hands that are washed between animals may be

TABLE 1. Glove related contact and associated morbidity and mortality for larval amphibians involved in laboratory experiments. All experimental animals were examined for signs of morbidity or mortality daily.

Species	Origin	N	Frequency of contact	Contact type[1]	Contact duration	Type of gloves used[2]	Response[3]	Reference

[3] Based on description of morbidity and mortality described by Cashins et al. (2008)

preferable to repeatedly using the same pair of gloves in some situations. Although both Mendez et al. (2008) and Cashins et al. (2008) conclude that using new pairs of gloves for each handled animal is important for preventing the inadvertent transmission of pathogens, we have become aware that some organizations and researchers are interpreting these studies as cause, or even justification, for not using gloves. We wish to emphasize that discontinuing glove use may unnecessarily lead to increased spread of harmful pathogens.

Although these studies indicate limitations and potential pitfalls of disposable gloves, their safe use remains an essential component of amphibian care and research. A variety of disposable gloves have been used extensively in the handling and care of larval amphibians in laboratory experiments (Table 1), in the field (Table 2), and in zoo settings (Table 3) without any adverse effects under conditions where morbidity or mortality would have been noticed. Additional examples documenting the non-injurious use of gloves appear in Cashins et al. (2008). These results make it clear that many glove types do not negatively affect many species of amphibian larvae. Given that the use of a new pair of gloves to handle each individual is a good method for preventing the transmission of pathogens, best practice should clearly be to handle larval amphibians using a new pair of gloves for each individual, of a type known to have no negative effects on that species. This can easily be done by initially determining which species are susceptible to which types or brands (or even batches) of gloves. Researchers can take a few simple steps to ensure that the gloves they use are not toxic to the amphibians they handle. We recommend a two-phase approach. If researchers have been handling larvae with disposable gloves in captivity or in a situation where individual larvae have been observed for 24 hours following contact and no adverse effects have been seen, then researchers should continue using those same gloves. However, they should remain vigilant for any unusual mortality by following the second phase of the following protocol.

First, researchers should conduct a simple experiment in which tadpoles or salamander larvae of a given species are handled using the gloves in question and then observed for 24 h for signs of morbidity or mortality. Sample sizes do not need to be especially large. Cashins et al. (2008) found that when gloves are toxic, ≥ 40% of the individuals were affected. Using 10% as a more conservative figure for the maximum number of individuals that may experience negative effects, a sample size of 29 provides a 95% probability of observing at least one morbid or dead animal if the gloves under examination have deleterious effects on the species being tested. For rare and endangered species, replicate individuals could be handled and observed sequentially so that individuals are not unnecessarily killed; a single death would suggest a problem with the gloves. It is important that each animal be handled with new gloves and housed in a separate container so that individuals are independent replicates. Note that plastic containers can leach bioactive contaminants (McDonald 2008), so it is worth scrutinizing containers too. Researchers should also use controls, in this case individuals handled with clean bare hands or with gloves that have been demonstrated to be safe with the species in question. Since there is no way to predict *a priori* which species will be affected

TABLE 2. Glove related contact and associated morbidity and mortality for amphibian larvae handled in field settings where the observation periods post-handling would have permitted detection of effects described by Cashins et al. (2008). These results are from ponds where animals could 1) be easily observed in the pond shallows for a period of time (>6 hours) post-glove contact (OBS); 2) where animals were resampled over the course of the season with a high recapture probability (RCAP); or 3) where the protocol requ□

[3] Based on description of morbidity and mortality described by Cashins et al. (2008)

by which gloves, this experiment should be conducted with every species to be handled using each type (e.g., latex, nitrile, or vinyl) and brand of glove that will be used. If it is impossible to hold individuals of a given species for 24 h, a sister species may be used. Given the potential for batch-to-batch variation in the manufacturing process, it may be preferable to order large batches of gloves after finding one that does not seem to cause mortality.

Second, once a suitable type and brand of glove are identified, experiments should be used intermittently to test new batches of these gloves for safety. As confidence in the safety and quality control of the product is established then the testing could be less frequent.

There are several other simple steps that researchers should take to minimize the risk to amphibians. Cashins et al. (2008) found that rinsing vinyl gloves in water reduced their toxicity, so any protocol should include rinsing gloves in fresh water prior to handling animals. The water used for this purpose could be collected on site but should be discarded terrestrially. We also recommend researchers pay attention to where gloves are stored to avoid unnecessary risks of gloves coming within close proximity of volatile toxic substances. While we cannot control how and where gloves are stored before we receive them, we can avoid storing them near disinfectants, insecticides, or laboratory chemicals. Lastly, we as a community should watch for and report morbidity and mortality associated with handling tadpoles and larvae in the lab or field. These findings should be openly shared with others who work on amphibians in order to avoid unnecessary morbidity and mortality. Disposable gloves are an essential component of any animal hygiene protocol and by taking these simple steps researchers can ensure that they help, rather than harm, the animals we study.

TABLE 3. Amphibian species at the Detroit Zoo that have been repeatedly handled using gloved hands and otherwise exposed to gloves during husbandry and veterinary care while in the larval lifestage. All animals are checked daily as part of routine care and husbandry. For several years, powdered latex gloves have been primarily used although infrequently non-powdered nitrile gloves are used. In no instance has glove-related morbidity or mortality as described by Cashins et al. (2008) ever been detected. Reference for all information in Table 3 is R. Johnson and D. Schock, personal observations.

The presence of suitable habitat is an important factor in the conservation of rare species (Loehle and Li 1996; Primack 2002; Smith 1996; Tilman et al. 1994). As such, in order to effectively work toward wildlife conservation, it is important to understand the habitat requirements of the species in question. Recent studies have suggested that landscape-level habitat factors, or macrohabitat, may be critical to determine the distribution of snake species native to Midwestern prairies (Cagle 2008). Alternatively, past research has shown that microhabitat selection is of greater importance than landscape-level habitat selection in a non-prairie species; the eastern Massasauga, *Sistrurus catenatus catenatus* (Harvey and Weatherhead 2006). Other studies have shown that certain snake species select habitat at several scales (Blouin-Demers and Weatherhead 2001; Reinert 1993; Row and Blouin-Demers 2006; Sperry and Weatherhead 2009; Wund et al. 2007).

Bullsnakes (*Pituophis catenifer sayi*) are considered a species of conservation concern in most upper Midwestern states. Thorough studies on the habitats selected by members of the genus *Pituophis*, including Bullsnakes, are rare. Much of the existing information on Bullsnakes in the upper Midwest comes from field guides, which report that it associates primarily with open-canopied, xeric habitats such as prairies and grasslands (Oldfield and Moriarty 1994; Phillips et al. 1999; Vogt 1981, *but see* Kapfer et al. 2008a, b, c). Although anecdotal observations of Bullsnake habitat associations can offer insight into their habitat preferences, this type of information does not support a thorough understanding of ecology. Rigorous, multi-year research on habitat selection at multiple scales is necessary to achieve this. The lack of detailed information is a significant hindrance to understanding the ecology of this species.

Bullsnakes have recently been reported to show a strong preference for open, south- to west-facing bluff slopes, rather than prairie or grassland (Kapfer et al. 2008c). This habitat is characterized by significant topographic relief, rocky soils and outcroppings, no overstory vegetation, and ground vegetation consisting of mostly short, herbaceous species, with occasional clumps of taller woody species. Although landscape-level habitat preferences have been reported for this species in the upper Midwest (Kapfer et al. 2008c), preferred microhabitat parameters remain largely unknown. Therefore, the main objective of this research was to use radiotelemetry to determine the microhabitat preferences, if any, of Bullsnakes in the upper Midwestern United States. We predicted that selection on a microhabitat scale would occur in Bullsnakes and that, based on previous research of macrohabitat preferences in this species (Kapfer et al. 2008c), selection would correspond with characteristics typical of preferred macrohabitats. As such, we predicted that favored microhabitats would likely have high rock cover, open canopy, and mostly herbaceous vegetation. Because this previous research on macrohabitat also found little difference between male and female preferences, we also predicted that males and females would not differ in microhabitat selection. We did, however, believe the microhabitat variables favored by males and females would differ from that measured at randomly selected locations.

Methods.—The study site, located in southwestern Wisconsin, was ca. 8943 ha in size. This area consisted of a mosaic of natural, managed, fallow, agricultural and residential habitats (Kapfer et al. 2008c). Managed habitat (mostly sand prairie, savanna, and open bluff sides) was kept in an early state of vegetative succession through a combination of herbicide application, removal of aggressive or invasive plant species and a prescribed burning regimen. Although open bluff sides comprised only a small portion of the managed property, it was the preferred macrohabitat of Bullsnakes (Kapfer et al. 2008c). The unmanaged habitat within the study area was dominated by closed-canopy bluff side forest and agriculture (row crop and pasture), with small components of non-bluff deciduous woodlots and residential property also sporadically present on the landscape.

We captured adult Bullsnakes opportunistically by hand during emergence from winter dormancy. We surgically implanted radio transmitters (models SI-2 or AI-2; Holohil Systems; Carp, Ontario, Canada) following the methods of Reinert and Cundall (1982). We released radio-tagged individuals approximately 48 h post-surgery and relocated them at least weekly throughout the duration of their active season (early-April to mid-October, 2003–2005) via radio receiver and three-element Yagi antenna (Advanced Telemetry Systems, Isanti, Minnesota, USA). Fieldwork was conducted from 0900 h to 1700 h. The amount of time spent tracking snakes within a given day varied widely, as did the times at which snakes were relocated.

Each time we located individuals, we measured several structural microhabitat variables within a 1.0 m^2 area centered on the location of snakes. These included the percent area covered with exposed rock, non-woody vegetation, woody vegetation, leaf litter, and woody vegetative debris. Vegetation height was also measured at four random positions within the same 1.0 m^2 area and averaged per snake location. We used a convex densiometer to measure canopy closure (Ben Meadows, Atlanta, Georgia, USA). We selected these microhabitat parameters based on past studies of snake habitat selection, but modified them to suit this study (Blouin-Demers and Weatherhead 2001; Blouin-Demers et al. 2007; Reinert 1984; Reinert 1993). We took care to ensure that

radio-tagged snakes were not disturbed while recording habitat information. On occasions where an individual snake was disturbed, we recorded microhabitat parameters at the location it had been observed prior to disturbance. If this could not be determined, we did not collect microhabitat data for that particular observation. We recorded data for both male and female snakes. Because we discovered that all female Bullsnakes were gravid during each year, we did not further separate them into "females" and "gravid females" for analyses.

We measured microhabitat parameters at 100 random locations, determined via Geographical Information Systems (GIS). We placed random data points only in habitats where snakes had been previously located during the first year of tracking, which included all habitats available within the designated study area. We then compared microhabitat data from random locations to microhabitat variables measured in association with male and female snake observations via discriminant function analysis (DFA, alpha to enter of 0.001) as in other studies (Blouin-Demers and Weatherhead 2001; Reinert 1984; Reinert 1993; Wund et al. 2007). In addition, a multiple analysis of variance (MANOVA) was conducted on the DFA scores, followed by a post-hoc pair-wise comparison with a Bonferroni correction to determine if differences existed among males, females and random locations in microhabitat variables preferred (Reinert 1984; Wund et al. 2007). We conducted all statistical analyses in Systat v. 10.0 (Point Richmond, California).

Results.—The number of snakes tracked in each year varied (2003 = 12 males, 8 females; 2004 = 9 males, 5 females; 2005 = 10 males, 5 females). We collectively located radio-tagged Bullsnakes a total of 310 times in 2003, 189 times in 204, and 291 times in 2005, and the mean number of locations recorded annually for an individual was 16.1 (± 3.8 SD). Conditions suitable to record microhabitat data occurred on 740 of these occasions (females, N = 281; males, N = 459).

Of the habitat variables associated with snake observations, the most common were consistent with open bluff sides. For example, the mean percentage of non-woody vegetation was largest among variables measured (41–47.6%), while mean vegetation height (35.5–37.3 cm) and tree canopy closure (~18%) associated with snake locations were small compared to the rest of the landscape (Table 1). The DFA revealed that males, females, and randomly sampled points could be distinguished using the microhabitat variables measured at each location (Wilk's $\lambda = 0.949$, $F = 3.176$, df = 14, 1684, $P = <0.001$). However, discriminant function 1 was a stronger discriminator (eigenvalue = 0.053) than discriminant function 2 (eigenvalue = 0.001). Several of the variables along the first discriminant axis influenced the distribution of male and female snakes, and also differed from random locations: percent rock, percent woody debris, and percent woody vegetation (Table 2; Fig. 1). In general, males exhibited a moderate preference for rock, woody debris and woody vegetation cover, which did not occur in females or random locations (Fig. 1). The MANOVA performed on the DFA scores indicated that males, females and random locations differed in their habitat association along the first discriminant axis, but not along the second (Wilk's $\lambda = 0.949$, $F = 11.182$, df = 4, 1694, $P = <0.001$). A Post-hoc, pair-wise comparison among groups with a Bonferroni correction indicated that, along the first discriminant axis, females differed from males (P = <0.001), females differed from random locations (P = 0.005) and males differed from random locations (P = <0.001). No significant difference was found among groups along the second discriminant axis (all comparisons P = 1.000). We recommend caution when interpreting our results, as a low percentage of jackknifed classification cases were predicted correctly by this analysis, particularly for females (females = 6%, males = 47% and random locations = 71%).

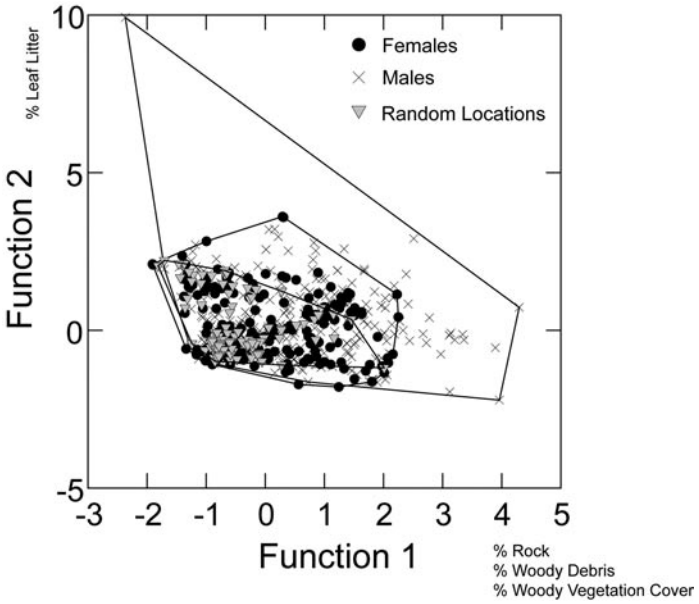

FIG. 1. Discriminant function plot of male and female Bullsnake (*Pituophis catenifer sayi*) and random location scores in southwestern Wisconsin, with convex hulls delineating the data clusters for each group.

Discussion.—These findings are the first, to our knowledge, to specifically address Bullsnake microhabitat selection. Some of our findings support the hypothesis that Bullsnakes

TABLE 1. Microhabitat parameters (% of 1.0 m^2 area centered on snake location ± 1 SD) recorded in association with male and female Bullsnake (*Pituophis catenifer sayi*) observations in southwestern Wisconsin.

	Males	Females	Random Locations
Rock	20.9 (± 34.4)	16.1 (± 31.9)	9.8 (± 23.2)
Leaf Litter	18.4 (± 36.7)	17.9 (± 33.71)	20.1 (± 36.4)
Non-woody Vegetation Cover	40.8 (± 38.2)	46.9 (± 39.7)	53.2 (± 37.1)
Woody Debris	13.5 (± 26.5)	9.6 (± 22.7)	4.6 (± 13.3)

Ave. Vegetation Height (cm)	37.3 (± 32.6)	35.4 (± 35.2)	34.3 (± 30.0)
Canopy Closure	19.2 (± 34.1)	18.9 (± 33.2)	21.6 (± 38.4)

TABLE 2. Summary statistics for the two canonical discriminant functions, standardized by within variances, for microhabitat variables measured while radio tracking Bullsnakes (*Pituophis catenifer sayi*) in southwestern Wisconsin.

Variable	Function 1	Function 2
% Rock	0.661	0.356
% Leaf Litter	-0.179	0.946
% Non-woody veg. cover	0.049	-0.175
% Woody debris	0.698	-0.244
% Woody veg. cover	0.479	-0.277
Vegetation Height	0.159	0.377
Canopy Closure	-0.129	0.017
	Canonical Scores of Group Means	
	Function 1	Function 2
Females	-0.104	-0.040
Males	0.182	0.014
Random Locations	-0.487	0.044
Eigenvalues	0.053	0.001

select microhabitat characteristics typically found in preferred macrohabitats (open bluff sides; Kapfer et al. 2008c). For example, non-woody herbaceous vegetation often found on open bluff sides was abundant compared to other habitat variables (Table 1). On average, 40% to nearly 50% of the 1.0 m^2 area immediately associated with snakes consisted of non-woody vegetation (Table 1). In addition, a positive association by males with rock cover was observed in the DFA, which is expected based on the prevalence of exposed rock outcroppings and rocky substrate on open bluff sides.

Males also exhibited a preference for woody debris and woody vegetation cover, which are not typically abundant on managed open bluff sides. Yet, woody debris does occur sporadically in this macrohabitat, and is occasionally used as cover by some snake species. The reason females do not exhibit preferences for these same microhabitat variables is unknown, as males and females were not found to substantially differ in their macrohabitat selection (Kapfer et al. 2008c), although females were found to prefer one additional habitat to males (savanna) in one of three years. However, gravid females have greater mean body temperatures than males (Kapfer et al. 2008a). To achieve this, females may seek out warmer microhabitats and less often use cover from woody vegetation or debris. Our prediction that males and females would prefer similar microhabitats was not supported, while our prediction that snakes would differ significantly from random locations was supported. In general, due to low eigenvalues and low percentages of correctly predicted jackknifed classification scores, the ability of our analyses to discriminate between these groups based on microhabitat variables was relatively low. Therefore, our analysis indicates that, although the DFA results support the prediction that Bullsnakes exhibit selection at the microhabitat scale, this selection is not strong. Therefore, it appears that microhabitat variables may not substantially influence habitat selection in this species. If true, it may be adequate to measure only macrohabitat preferences (or landscape level preferences) to effectively understand the Bullsnake's habitat needs. This also suggests that habitat management for Bullsnakes should focus on habitat communities rather than microhabitat composition. Other recently published studies have also suggested that effective snake conservation efforts in prairies of the midwestern United States should focus on determining landscape-level habitat preferences (Cagle 2008).

The Green Salamander, *Aneides aeneus*, is a federal species of concern and in North Carolina it is listed as endangered (LeGrand et al. 2006). The importance of suitable rock crevices to Green Salamanders has been noted by many researchers (e.g. Bruce 1968; Gordon 1952; Gordon and Smith 1949; Netting and Richmond 1932; Petranka 1998). Green Salamanders generally use two types of rock crevices, which have been described by Gordon (1952) as "breeding" and "transitory" crevices. Breeding crevices are used primarily by gravid females for egg laying and brooding eggs and hatchlings (Canterbury and Pauley 1994; Gordon 1952; Petranka 1998). Transitory crevices are used by juveniles, males, and non-breeding females and are thought to serve as refuges that provide stable microclimatic conditions (Cupp 1980; Gordon 1952). Cupp (1980) postulated that these specialized rock crevices form the basis of a Green Salamander's territory, as most males and females he observed occupied and defended individual crevices throughout much of the year.

Currently, very little published data are available on the characteristics of rock crevices used by Green Salamanders. To our knowledge, Gordon (1952) provided the only comprehensive data on rock crevices used by Green Salamanders. In his study, he quantified 17 attributes of breeding (N = 16) and transitory crevices (N = 30) used by two populations of Green Salamanders in North Carolina. However, only limited inferences on the relative importance of selected attributes can be drawn from Gordon's (1952) study because no comparisons were made to an attribute's availability in the surrounding environment. In this study, we quantified the attributes of rock crevices used by a population of Green Salamanders on the Blue Ridge Escarpment and investigated whether the attributes selected differed from those available in the surrounding environment.

Materials and Methods

Study Site.—We conducted our study at a rock complex at Heady Mountain Gap in the Highlands District of the Nantahala National Forest, Jackson County, North Carolina (elevation 1036 m). The site was chosen because it had an abundance of Green Salamanders (L. Williams, unpubl. data) and it was accessible. The rock complex was part of the Biotite gneiss unit of the Alligator Back Formation, which was metamorphosed to Amphibolite Facies in the Blue Ridge Belt (North Carolina Geologic Survey 1985). Temperatures of the Blue Ridge Escarpment are considered mild and annual precipitation is the highest in eastern North America, ranging from 215–250 cm (White et al. 1998).

The rock complex consisted of three separate outcrops (96 m^2, 50 m^2, and 35 m^2) approximately 15 m apart. The site was located on a southwest-facing slope surrounded by relatively mature mixed-hardwood forest, with a closed canopy and thick shrub layer. Dominant canopy species included Northern Red Oak (*Quercus rubra*), Chestnut Oak (*Q. prinus*), Red Maple (*Acer rubrum*), and Tulip Poplar (*Liriodendron tulipifera*). Rhododendron (*Rhododendron maximum*) and Mountain Laurel (*Kalmia latifolia*) comprised the shrub layer.

Crevice surveys and measurements.—We conducted four diurnal and three nocturnal searches for crevices occupied by Green Salamanders from 12 May to 3 June 2006. Searches were generally conducted every 6 d. Diurnal searches were conducted between 1200–1500 h, and nocturnal searches were conducted between 2000–2200 h. All crevices in each rock outcrop were systematically searched using a flashlight. Searches typically occurred on partly cloudy to clear days with the exception of one diurnal search that occurred during a rain event. Air temperatures during searches ranged from 18–24°C. We measured the distance of each crevice occupied by a Green Salamander (and each corresponding unoccupied crevice, see details below) to a marked reference point on each rock outcrop in order to track and identify all crevices used in the study.

We restricted our study to those crevices most likely used as transitory crevices, because crevices used for breeding may have dif-

ferent characteristics (Gordon 1952). Green Salamanders in the southern Appalachians mate in late May and early June (Canterbury and Pauley 1994; Gordon 1952), with male-gravid female pairs occupying breeding crevices for 3–7 d (Canterbury and Pauley 1994). Eggs are laid during the first two weeks of June (Canterbury and Pauley 1994; Gordon 1952). Therefore, we only quantified crevices that contained one occupant and no evidence of eggs. We visually categorized the age of individuals in crevices as either juvenile (< 45 mm snout to vent length, SVL) or adult (> 45 mm SVL; Juterbock 1989). We did not determine the sex of individuals because of the difficulty and invasiveness of capturing animals (Gordon 1961; Netting and Richmond 1932).

For each occupied crevice, we measured the total length (measured using a string placed along the bottom edge of the crevice opening on the rock face), maximum depth (measured using a flattened wooden probe), maximum opening width (measured using a tape measure), mean depth and mean opening width (calculated using measurements at three equidistant points along the crevice), drip-edge (horizontal distance of cover provided by the closest overhanging ledge above the crevice, measured using a plumb bob and tape measure), slope (angle of crevice above horizontal estimated using a protractor and level), and height above the ground (measured from the lowest point of the crevice opening on the rock face).

For each occupied crevice, we identified a corresponding unoccupied crevice located 1 m from each occupied crevice to determine whether the attributes of occupied crevices differed from those available on the rock outcrops. We used a random numbers table to determine the direction (0–360°) an unoccupied crevice would be located from an occupied crevice. An unoccupied crevice was determined suitable if its opening was at least 0.3 cm wide and large enough for a juvenile Green Salamander to use. If a suitable crevice was not located at the 1 m point, we continued along the random direction until a suitable crevice was found. In the event there was no suitable crevice along the random direction, we generated a new random direction and repeated the procedure until a suitable crevice was located. Once an unoccupied crevice was selected, data were recorded as described above. We tracked all unoccupied crevices throughout the study and none were found to be occupied during any of the searches.

Analyses.—We conducted a conditional logistical regression analysis for matched pairs to examine which characteristics increased the probability that a salamander would select the occupied crevices instead of the unoccupied ones (Allison 1999). We analyzed attributes separately to avoid over-fitting. We excluded crevice height from the analysis because height of unoccupied crevices was dependent on height of occupied crevices. We used the likelihood-ratio chi-squared statistic to test the null hypothesis on no selection based on a given attribute with a significance level of 0.05. The PHREG procedure in Statistical Analysis System (SAS) was used for all calculations (SAS Institute Inc. 2004). To examine whether Green Salamanders used crevices at particular heights, a t-confidence interval for the mean height of the occupied crevices at each rock outcrop was calculated and compared to the middle height of each rock.

Table 1. Means (SD) of attributes of 15 occupied and 15 unoccupied rock crevices in a population of Green Salamanders at Heady Mountain Gap, Nantahala National Forest, North Carolina.

Attribute	Occupied	Unoccupied	χ^2	P-value[1]
Length (cm)	18.2 (8.9)	13.2 (6.1)	2.35	0.13
Mean opening width (cm)	1.8 (1.4)	2.6 (1.8)	4.14	0.04
Mean depth (cm)	6.1 (2.9)	5.5 (3.0)	0.27	0.60
Maximum opening width (cm)	2.1 (1.5)	3.7 (3.2)	5.95	0.01
Maximum depth (cm)	7.2 (2.8)	6.7 (3.4)	0.24	0.63
Drip-edge (cm)	19.0 (23.0)	24.9 (41.2)	0.42	0.52
Slope (°)	24.5 (27.7)	23.3 (28.8)	0.02	0.89

[1]Likelihood-ratio chi-square tests were used to compare attributes of occupied and unoccupied crevices (P-value < 0.05 was considered significant for all tests).

Results

We identified fifteen occupied crevices during our study, with a maximum of six occupied crevices during any one search. All crevice occupants were adults. Nine crevices were occupied during diurnal searches, and six were occupied during nocturnal searches. Of the fifteen crevices, five were occupied during at least one diurnal and one nocturnal search. Occupied crevices had smaller mean opening widths ($P = 0.04$) and smaller maximum opening widths ($P = 0.01$) than unoccupied crevices (Table 1). No other differences were found between any of the other attributes compared (all $P > 0.12$; Table 1).

Outcrop 1 (total height of 701 cm) had four occupied crevices, with a mean crevice height of 82.6 cm (95% CI = 18.2, 146.9). Outcrop 2 (total height of 274 cm) had ten occupied crevices, with a mean crevice height of 133.3 cm (95% CI = 103.0, 139.3). Outcrop 3 (total height of 264 cm) had a single occupied crevice at a height of 172.2 cm.

The confidence interval for Outcrop 2 contained the middle height of the outcrop, but the upper limit of the confidence interval for Outcrop 1 was significantly lower than the middle height of the rock ($P = 0.0009$).

Discussion

Transitory crevices have been characterized as refuges used by Green Salamanders to avoid periods of low humidity (Cupp 1980; Gordon 1952). Many researchers have suggested that narrow crevices are a primary component of suitable Green Salamander habitat (Bruce 1968; Gordon 1952; Gordon and Smith 1949; Netting and Richmond 1932; Petranka 1998). In our study, Green Salamanders selected crevices with smaller openings than were available in the surrounding habitat, supporting the importance of narrow crevices to Green Salamanders. Crevices with narrow openings may be preferred by Green Salamanders because they are more efficient at maintaining high relative humidity levels and constant temperatures than crevices with larger openings. Crevices used by Green

Salamanders have been found to maintain high relative humidity levels and moderate extreme temperature fluctuations relative to conditions outside the crevices (Canterbury 1991; Gordon 1952; Snyder 1971). Green Salamanders also may select narrow crevices to avoid direct competition with other salamanders that occasionally inhabit rock crevices such as woodland salamanders (*Plethodon* spp.; Gordon 1952). Green Salamanders are uniquely adapted for inhabiting narrow crevices because of their flattened bodies (Conant and Collins 1998; Petranka 1998).

It has been suggested that Green Salamanders select higher crevices on rocks because their greater climbing ability allows them to avoid competition when other crevice-dwelling plethodontid salamanders are present (Cliburn and Porter 1986; Cliburn and Porter 1987; Pauley and Watson 2005). This is supported by field observations and laboratory tests by Cliburn and Porter (1987) that found Green Salamanders stratified vertically in the presence of *Plethodon glutinosus*, with Green Salamanders selecting significantly higher crevices. Our findings comparing the confidence intervals of the heights of occupied crevices to the middle height of each rock outcrop suggest that Green Salamanders in our study did not vertically stratify, and on Outcrop 1 used crevices lower on the rock than expected by chance. The lack of vertical stratification is further supported by the fact that no other species of salamander were found during our study. It should be noted, however, that these results assume that suitable crevices were distributed evenly at all heights of the rocks. Although we did not quantify the heights of all suitable crevices, observations indicated that they were available throughout the entire rock faces.

The dimensions of occupied crevices in our study (e.g., length, mean opening width, and depth) were comparable to those reported by Gordon (1952) for two populations in North Carolina, highlighting the specialized and specific habitat requirements of this species. Many of the attributes examined in our study did not differ from those available in the surrounding habitat, suggesting that these attributes may not be as important to Green Salamanders choosing crevices. However, because of our small sample size, these findings should be viewed tentatively until a broader range of habitats are sampled.

Acknowledgments.—We thank D. Danner and J. Owenby for logistical support, A. Smith, J. Harrelson, J. Short, J. Dahlke, and K. Blanchard-Reid for field assistance, and J. Miller, I. Rossell, and J. Petranka for reviewing the manuscript. Financial assistance was provided by the Undergraduate Research Program at the University of North Carolina at Asheville.

Amphiuma means is common on Cumberland Island, the largest and southernmost barrier island off the coast of Georgia. A number of Two-toed Amphiumas have been preserved over the years by CR, and provided a source for examination of their food habits. Knowledge of the diet is basic to understanding their biology and natural history. The purpose of this paper is to examine the food of *Amphiuma means* on Cumberland Island, Georgia, and to compare the results with those of previous studies on this species elsewhere.

Most reports on the diet of *A. means* have been generalized into broad categories of food items such as crayfish, frogs, earthworms, and salamanders (Martof et al. 1980; Mount 1975) or involve few individuals (Duellman and Schwartz 1958; Enge 1998). Hamilton (1950) provided a detailed account of the major food groups of 36 individuals from Florida and South Carolina. Machovina (1994) identified food items from 94 *Amphiuma* from the Everglades, and also reported on seasonality of the diet. Duellman and Schwartz (1958) examined 11 individuals, but only 6 provided information on food.

Materials and Methods.—Cumberland Island is a barrier island with freshwater sloughs occurring behind the beach dune complex. The sloughs are relics of the primary dune system and may be extensive, although shallow and frequently dry. The water in these systems reflects groundwater level, the recharge of which is provided solely by rainwater. During periods of drought, aquatic flora and fauna are supplanted by *Eupatorium capillifolium* (dog fennel), grasses, and other terrestrial species, and blowing sand may block the usual drainage to the sea, especially where the dune system is compromised by feral cattle or horses (pers. obs.). Storms or heavy rainfall may cause the water level to rise above the confining sand dunes. In that case, the water may breach the dunes and increase in velocity as it deepens its channel to the sea. This flush of usually fairly stagnant water may catch animals unaware or they may deliberately take advantage of it to disperse. Many animals end up in the sea. For several days after such a breach, freshwater animals (mostly fish but including *A. means*) may be found stranded at the wrack line. Osmoregulation of *Amphiuma means* is unable to cope with exposure to saltwater (pers. obs.) and they usually die quickly; thus, the gut contents of stranded individuals reflect normal feeding in their freshwater environment.

All individuals of *Amphiuma means* included in this study were collected between 1983 and 1996, and all were associated with temporary fresh water systems. Many (N = 62) were salvaged from the ocean beach after exposure to salt water and others were mortalities of modified funnel traps during a behavior study. Feces were collected from four live animals. Male snout–vent length averaged 544 mm (range 383–735, N = 38), and total length averaged 675 mm (range 490–935, N = 36). Female snout-vent length averaged 513 mm (range 295–641, N = 27) and total length averaged 628 mm (range 385–828, N = 26). Measurements were taken from both the preserved and live animals. Tails had been mutilated in some cases; therefore the numbers measured for total length are less than those measured for snout-vent length. The specimens are preserved in the Cumberland Island Museum.

Stomach and intestinal contents were collected separately from 65 preserved specimens. All were treated as separate samples. Twelve individuals had materials in the stomach only, 37 had food in the intestines only, and 12 had food in both the stomach and the intestines. Feces were collected from four live animals. This totaled 77 samples. We also examined five individuals that had nothing in either the stomach or intestines. Food items were identified with the aid of a dissecting microscope to the lowest possible taxon. The percent volume of each component in each sample was visually estimated (Whitaker 1988), and the data were averaged for a total percent volume for each item recorded. Percent frequency represents the number of animals which contained each item, calculated as a percentage of the total. Calculating only percent frequency has the potential to be misleading especially when there is great diversity in prey numbers and size. Seasons were defined as spring: March–May, N = 11; summer: June–August, N = 23; autumn: September–November, N = 43; and winter: December–February, N = 0.

Results.—The items identified (35) in 77 Two-toed Amphiuma food samples from Cumberland Island, Georgia (Table 1) were insects (16), other invertebrates (6), vertebrates (12), and plant materials (1). Six different plant items were actually identified, but were presumed to have been incidentally ingested. The three most predominant foods both in percent volume and percent frequency were: crayfish, *Procambarus paeninsulanus* (46.0% volume, 59.7% frequency), insects (31.4% volume), and amphibians (11.0% volume).

The most predominant insect groups represented were: Coleoptera (11.5% volume), including unidentified adults; Hemiptera (5.1%); Diptera (4.9%), Lepidoptera (3.4%); Orthoptera (0.7%); Odonata (0.2%). Other invertebrates included Chilopoda (0.5%), Araneae (0.1%), Annelida (1.6%), and Mollusca (0.2%).

Vertebrates (16.6% volume) were represented by Amphibia (11.0%), Reptilia (1.8%), and Osteichthyes (2.2%). The majority of the amphibians consumed were salamanders *Amphiuma means* (6.9% volume, 11.7% frequency), *Notophthalmus viridescens* (Eastern Newt) (1.4%, 2.6%), and shed skin (0.1%, 2.6%), probably of *Amphiuma* (Brode and Gunter 1959). The remainder included *Rana grylio* (Pig Frog) (1.9% volume) and tadpoles (0.6%).

Among the reptiles consumed were *Nerodia fasciata* (Southern Watersnake), which contributed the greatest volume (1.3%) and was more frequently captured (2.6%) than unidentified lizards (0.3% volume), lizard eggs (0.1%), or turtle eggs (0.1%). The fishes identified were all mosquitofish, *Gambusia affinis*.

The percentage of food items changed seasonally (Table 2). Crayfish were the most important food item by volume in spring (60.5%)

TABLE 1. Food of the Two-toed Amphiuma, *Amphiuma means*, from Cumberland Island, Camden County, Georgia (N = 77).

Food item	% Volume	% Frequency
Invertebrates other than insects	(48.4)	
Crustacea (*Procambarus paeninsulanus*)	46.0	59.7
Chilopoda	0.5	1.3

Vegetation	1.9	2.4	5.2	3.9
	100.1	99.9	99.9	100.2

and summer (65.2%), but were much lower in fall (32.5%). Insects were low in spring (9.9%) and summer (14.1%) but increased greatly in fall (45.5%), apparently being much more heavily eaten at that time perhaps because they were more abundant. Reptiles were eaten in spring (9.6%), but not much later. Amphibians were the second most eaten item in spring (13.5%) and summer (15.2%), third after insects and crayfish in autumn.

Data on sex were not available for all the amphiumas, but we did have information on 35 males and 28 females. The greatest difference was in the amounts of crayfish eaten by males (57.4% volume) and by females (37.8%). However, larger individuals ate more crayfish, and males averaged larger than females which could account for that difference. Data on other of the more important foods were Diptera (5.6% males, 5.5% females), Carabidae (4.4%, 0%), Hydrophilidae (4.6%, 0%), vegetation (3.6%, 3.9%), Nepidae (1.7%, 4.1%), *Amphiuma* (6.6%, 10.5%), Lepidopteran larvae (2.4%, 0.9%), *Rana* (0%, 2.9%), Scarab larvae (0%, 2.1%), and Chilopoda (2.3%, 0%). There are some differences, especially a few cases where members of one sex had eaten an item, and the other none (Carabidae, Hydrophilidae, *Rana*, and scarabaeid larvae), but the samples were too small to mean much.

Discussion.—Hamilton (1950) found insects most important in volume (33.8%) and frequency (52.8%) in his sample, with crayfish second in frequency (25.0%) but fifth in percent volume (12.8%). Other items were amphibians (19.7% volume, 19.4% frequency), reptiles (12.4%, 16.7%), fish (17.6%, 19.4%), molluscs (2.4%, 11.1%), and arachnids (1.3%, 2.8%). Machovina (1994) found crayfish to be first in frequency (57.0%) followed by insects (49.1%), amphibians (8.3%), reptiles (4.0%), fish (20.0%), and vegetation (9.4%) with no estimate of percent volume provided. The greatest differences in the findings of these studies and the present one is the reduced use of amphibians by the Everglades population (8.3% frequency) compared with that of Hamilton (1950) from widely separated geographic areas (Charleston, South Carolina, and Fort Myers, Florida, 19.4%) and ours on Cumberland Island, Georgia (22.1%). The consumption of reptiles was more similar between the Cumberland Island sample (6.5%) and the Everglades collection (4.0%) than Hamilton's (16.7%), and the use of fish was greatly reduced on Cumberland Island (7.8%) compared with the other localities (Hamilton 19.4%, Machovina 20.0%). This is because freshwater fish are uncommon on Cumberland Island and usually include primarily *Gambusia* in the sloughs and temporary ponds of amphiuma habitats.

Hamilton (1950) did not calculate values for the insect groups he recorded, but he did rank them. Midges (Chironomidae) were found by Hamilton but not represented in the other studies. Machovina (1994) calculated percent frequency of the groups but found less diversity than in our study. He found Belostomatidae (Hemiptera) in his Everglades sample but it was not found in the

other studies, and two of the three top-ranking insect categories in our study, Nepidae (Hemiptera) and miscellaneous Lepidoptera and lepidopteran larvae, were not found in the other studies. The majority of the insects consumed by amphiuma in all three studies were beetles (Order Coleoptera) with the families Dytiscidae and Hydrophilidae most prominent. The only other group represented in all three studies was Orthoptera, with a low occurrence. Some plant material was present, but we think that most of it was ingested incidentally, in or with other foods. Data from Duellman and Schwartz (1958) are few but similar to ours. Six individuals had food as follows: one had 4 syrphid larvae, one had 2 dragonfly naiads, one had 5 aquatic beetles (Dytiscidae, Hydrophilidae), one had eaten fish, *Mollienesia latipinna*, and one had eaten crayfish. It is interesting that the fish found were also in the family Poeciliidae, the same as ours.

Availability and size of both predator and prey are important factors contributing to *Amphiuma* diet (Dundee and Rossman 1989), yet few reports have specifically correlated size of animal with type of prey. Hamilton (1950) provided the range of sizes of his individuals but not the average length, while Machovina (1994) found a change in diet from insects to fish and crayfish in larger animals (over 350 mm SVL). In our individuals with a total length of less than 500 mm, the volume and frequency of crayfish in the diet was 5%, but the number of animals available for analysis was low (N = 4). Insects and fish were the two most important items of the smaller *Amphiuma*. Crayfish (76%) were slightly more predominant than insects (62%) in frequency in animals over 700 mm in total length (N = 21), but crayfish (57.2%) composed a much greater percent volume than insects (16.0%).

Collecting methods and season of capture may bias a sample for animal size. All our animals below 400 mm total length (N = 7) were taken in autumn. Size of trap mesh and vulnerability of small animals to predators on the ocean beach could have biased our collections. Machovina (1994) did not find a seasonal change in diet in the Everglades, but seasonal changes in diet are more likely to occur in the northern part of the animal's range where temperature changes are more pronounced.

Homonota andicola is a small (45 mm maximum SVL), terrestrial, nocturnal gecko of the mountainous regions of west-central Argentina (Cei 1986). Because the species has been virtually unstudied it is currently defined as a species for which "insufficient knowledge" exists (Lavilla et al. 2000). In fact, the only ecological information available about *H. andicola* are the comments in the original species description (Cei 1978), which simply state that it is a saxicolous lizard. Here, we provide the first ecological data for this species including aspects of its thermal ecology, diet, and reproduction. Fieldwork was conducted in January 2001 and January and March 2005 in the Valle de Chaschuil, Departamento Tinogasta, Provincia de Catamarca, Argentina (27.72777°S, 68.15305°W, WGS 84; 3200 m elev.). The habitat at our field site is characterized as Puna (Cabrera 1994) with rocky hillsides and sparse herbaceous and shrubby vegetation growing among the rock outcrops. The climate is generally cool and semiarid with broad daily thermal amplitude and high solar radiation (Boretto and Ibargüengoytía 2006).

We captured lizards by hand from under rocks. Lizard cloacal temperature (T_b), substratum temperature (T_s), and air (T_a) temperature were measured (± 0.1°C) within 5 seconds of capture with a rapid-reading mercury thermometer (Miller-Weber, New York, USA). For each capture, we recorded T_s at the point of observation, and T_a 1 cm above the surface of the substratum. We measured snout–vent length (SVL) with Vernier calipers (± 0.02 mm) and determined the sex of each specimen via visual inspection of enlarged swelling at the base of the tail. Thermal data were obtained on 1 January and 1 March 2005 between 0900 and 1900 h.

The lizards were fixed in 10% formalin and preserved in 70% ethanol no more than 4 hours from the time they were captured. Thereafter, the geckos were dissected and their gut contents and gonads were examined with the aid of a dissecting magnifying lens. Our diet analysis only considered items found in the stomachs and small intestines. Insects were identified to taxonomic order, and the maximum length and width of all items were measured with calipers (± 0.1 mm) to estimate their volume. We determined the relative importance of each item using the relative importance index (Pianka et al. 1971).

For females, we recorded the states of developing follicles (vitellogenic or non-vitellogenic) and the condition of the oviducts (enlarged or not enlarged).

We collected 27 *H. andicola* (16 males, 11 females). Mean SVL

TABLE 1. Diet composition in *Homonota andicola* (N = 27), with prey categories expressed as percentage by number (# = number of prey per category and percentage of the total number of prey), frequency of occurrence (percentage of lizards whose guts contained one or more prey), volume (in mm^3 and percentage of total volume) and IRI (index of relative importance).

Items	# (%)		Frequency (%)		Volume in mm^3 (%)		IRI	
	Male	Female	Male	Female	Male	Female	Male	Female
Diptera	3(5.5)	3(8.1)	6.2	27.2	42.4 (3.4)	42.4 (4)	55.9	330.1

Isoptera	3(5.5)	—	6.2	—	0.4(0.0)	—	34.8	—
Orthoptera	2(3.7)	1(2.7)	12.5	9.1	251.3(20.2)	125.6(11.8)	298.6	132.3
Mollusca	1(1.8)	—	6.2	—	5.2(0.4)	—	14.2	—
Hemiptera	1(1.8)	—	6.2	—	108.9(8.7)	—	66.2	—
Hymenoptera	3(5.55)	5(13.5)	18.7	27.3	1.6(0.1)	2.6(0.2)	106.4	375.1
Homoptera	1(1.8)	2(5.4)	6.2	18.2	5.2(0.4)	10.5(1)	14.2	116.2
Larvae								
Diptera	7(12.9)	3(8.1)	18.7	27.27	0.4(0.03)	0.2(0.0)	243.7	221.4
Lepidoptera	1(1.8)	3(8.1)	6.2	18.2	196.3(15.7)	589.1(55.6)	110.1	1158
Coleoptera	—	2(5.4)	—	9.1	—	28.3(2.7)	—	73.3
Aranea	5(9.2)	1(2.7)	18.7	9.1	0.6(0.05)	0.1(0.0)	174.4	24.65
Plants	—(50)	—(45.4)	—	—	—	—	—	—

was 39.9 mm (SD = 7.9, range: 24–47 mm) for males and 42.8 mm (SD = 2.8, range: 39–47 mm) for females. The sexes were dimorphic in body length (t = -1.15; P = 0.002). Mean body temperature of 18 *H. andicola* was 13.0ºC (SD = 5.3, range: 7.0–22.5ºC). Mean air temperature was 13.2ºC (SD = 2.7, range: 10.0–17.9ºC). Mean substrate temperature was 11.7ºC (SD = 3.8, range: 8.0–18.0). Body size was unrelated to T_b (Spearman rank correlation: r_s = -0.18, P = 0.46), but T_b was correlated with both T_s and T_a (r_s = 0.75, P = 0.002; r_s = 0.90, P < 0.0001, respectively). The mean T_b of *H. andicola* is lower than that recorded for other *Homonota* species: *H. fasciata* (T_b = 27.2°C; Aun and Martori 1994), *H. underwoodi* (T_b = 26.3°C; Marinero et al. 2003), and *H. darwinii* (T_b = 21.7°C, Ibargüengoytía et al. 2007). *Homonta andicola* appears to be to thermoconforming and highly dependent on the air and substratum temperatures.

We registered a total of nine prey item categories for both sexes. We analyzed diet separately for each sex because we found differences in the gut contents of males and females (Kolmogorov-Smirnov two sample test: D_{max} = 0.08; P = 0.005). The diet consisted predominantly of arthropods, with Lepidoptera and Coleoptera being the most important items for males and Coleoptera and larval Lepidoptera for females (Table 1). It is possible that these differences result from resource partitioning between the sexes, but we cannot affirm this due to the low number of our sample. Plants, including leaves and stems of *Ephedra breana*, were also eaten frequently by both sexes (Table 1). By contrast, other *Homonota* species studied to date do not eat plants (*H. fasciata*: Aun and Martori 1994; *H. fasciata* and *H. whitti*: Martori et al. 2002). Yet other Andean lizards in this region (e.g., *Pristidactylus scapulatus*: Acosta et al. 2004; *Liolaemus ruibali*: Villavicencio et al. 2005; and *Phymaturus antofagastensis*: Acosta et al. 2008) also eat *Ephedra* sp.

Reproductive females ranged from 40–47 mm in SVL. All the females sampled had nonvitellogenic follicles, 80% had enlarged oviducts in January 2001, and 25% in January and March 2005. These observations suggest that the female reproductive cycle ends by March.

All specimens were deposited in the Herpetology Collections of the Instituto y Museo de Ciencias Naturales of Universidad Nacional de San Juan (IMCN-UNSJ 4276–4302).

Acknowledgments.—We thank M. Hayes and Emily Taylor for comments and suggestions and CICITCA- 21E/831 for financial support. Thanks to Secretaría de Medio Ambiente of Catamarca Province for permits to collect.

Scientific and Traditional Conceptions of Snakes in Kenya: Herpetologists as Teacher Mentors

"We all have a duty to protect our environment and conserve biological diversity for posterity."
—Mwai Kibaki, President of the Republic of Kenya

The conservation of herpetofauna (reptiles and amphibians) through the teaching and understanding of biology, ecology, and environmental studies hinges on the ability of teachers to impart factual information about this misunderstood and sometimes feared group of animals. Unfortunately, knowledge about herpetofauna is too often based on misinformation or presented by individuals with limited knowledge who perpetuate misconceptions and superstitions (Gibbons 1983). Snakes, in particular, are one of the most feared and abused taxa within this group of animals (Gibbons et al. 2000; Greene 1997; Ricciuti 2001). Many people are simply unaware that most species of snakes are completely harmless and many species are ecologically beneficial.

Environmental education has been charged with integrating the aforementioned subject areas while fostering informed decision making abilities in school children and the population at large. Environmental education is defined as:

> A learning process that increases people's knowledge and awareness about the environment and associated challenges, develops the necessary skills and expertise to address the challenges, and fosters attitudes, motivations, and commitments to make informed decisions and take responsible action.
>
> (UNESCO, Tbilisi Declaration, 1978).

Conserving Earth's biodiversity is a longstanding goal of environmental education (Kenya Organization of Environmental Education [KOEE] 2006; North American Association For Environmental Education 2006). The United States and Kenya both recognize the need for environmental education and agree that biodiversity conservation is necessary to ensure a sustainable environment for all (American Association for the Advancement of Science 1993; KOEE 2006; National Science Teachers Association 2003). Conservation education can be considered a subset of environmental education and is frequently acknowledged as one of the primary antecedents of environmental education (Nash 1976). However, environmental education has treaded lightly when it comes to promoting action due to the fear of blurring the lines between teaching ecologically sound science and politically motivated or special interest group advocacy (see Tanner 1974; van Weelie and Wals 2002).

Over the last 30 years the term conservation has evolved from a resource management term to one that includes concern for the protection of the world's biodiversity, which agrees with the interests of environmental education. However, in this regard, conservation education takes concern for biodiversity one step further than environmental education by the admission of advocacy for, and the protection of, animals, plants and the necessary environments to sustain them. Museums and zoos worldwide have adopted a conservation education mission (Carr 2005). For example, according to the National Museums of Kenya's Director-General, Dr. Iddle Farah, "…our Museums' mission has expanded from one of passive collection and specialized scholarship to include active participation and commitment in meeting today's many needs of Kenyan society" (Accessed 2007 Oct 13 from: http://www.naturekenya.org/museums.htm). As an advocate for herpetofauna conservation, this study was based on a conservation education philosophy and also influenced why I chose teachers for my participants. I felt teachers would continue a positive message for snake conservation long after I had left. (My return in the spring of 2008 has born this out, as the primary participants are still teaching snake conservation lessons in their classrooms.)

I conducted a three-month descriptive qualitative study mid-September through mid-December 2005 to investigate conceptions of snakes among 60 rural southeast Kenyan teachers from five villages surrounding Mt. Kasigau. I used a narrative inquiry approach (Clandinin and Connelly 2000). I chose teachers as participants for this study as local community elders informed me that educators would have impunity from stigmatization from imparting scientific viewpoints about snakes and handling live snakes. The following research questions were used to guide this study:

1. How do Kasigau teachers conceptually relate to snakes?
2. How might Kasigau teachers' conceptual relationship with snakes change following exposure to scientific perspectives and experiences?

Three herpetologists and I traveled to the village of Bungule to facilitate herpetofauna conservation education opportunities for the teachers of Kasigau; the herpetologists were Patrick Malonza and Beryl Bwong of the National Museums of Kenya, and John Measey of the University of Antwerp. We conducted a herpetofauna professional development institute in order to facilitate encounters between Kasigau teachers, herpetologists and snakes; the institute consisted of all workshops and scientific experiences conducted by the visiting herpetologists or myself during the study period. During the course of this study 23 species of snakes were captured and kept temporarily for use during the aforementioned workshops

and additional in-depth training for the primary participants (see Table 1).

Visits by the herpetologists included one full-day (six-hour) workshop for 24 of the 60 teachers from the Kasigau area held in the village of Bungule during the beginning of the project, and three subsequent five-day visits by Patrick and John to mentor the principal participants. Additional half-day (three-hour) workshops were conducted at each of the five primary schools for those teachers who did not attend the first workshop. Therefore, all 60 teachers eventually received the same basic information about local herpetofauna. Of these, seven teachers (five males and two females) who showed the greatest interest in the study were invited to be primary participants, and received more exposure to scientific information as a result of the amount of time spent with the herpetologists and me. Of the seven, two teachers (hereafter referred to as principal participants) experienced the most opportunities to learn about snakes and spend time with visiting herpetologists and me. The primary participants spent additional time with me hunting for snakes and learning about snake identification and collecting techniques [i.e., one morning checking drift fences (4 h) and one full day searching for snakes and visiting at my banda handling live harmless snakes (six hours)]. The principal participants also read the book *Their Bood Runs Cold: Adventures with Reptiles and Amphibians* by Gibbons (1983) and one principal participant presented snake talks with live harmless snakes at each of the primary schools and the Taita Discovery Center (a nearby ecotourism lodge) during the last week of the study.

Workshop topics included: how to conduct a Visual Encounter Survey of microhabitats; the construction, maintenance, and monitoring of drift fences; identification of the various reptiles and amphibians indigenous to the region, including use of dichotomous keys and field guides; and methods museums use for preserving and cataloging reptile and amphibian specimens. Workshop facilitators modeled the use of such apparatus as snake sticks and snake tongs using live snakes. Experienced facilitators modeled how one should handle a venomous snake (puff adder; *Bitis arietans*) using a snake stick and snake tongs, as well as harmless snakes. Live nonvenomous snakes used for modeling purposes were the Speckled Green Snake (*Philothamnus punctatus*), Kenyan Sand Boa (*Eryx colubrinus*), Brown House Snake (*Lamprophis fuliginosus*), and the Cape Wolf Snake (*Lycophidion capense*). We stressed use of obvious morphological characteristics for identifying the different snake species, especially ways to distinguish venomous snakes from nonvenomous snakes.

Generally speaking, the traditional conceptions of the Wakasigau about snakes included fear, aversion, and loathing (Wakasigau refers to the people living in the five villages surrounding Mt. Kasigau; Bungule, Jora, Rukanga, Kiteghe and Makwasinyi). Snakes encountered by the Wakasigau are usually killed.

I collected narratives describing the conceptions of snakes from seven rural Kenyan teachers and other influential community members living in Kasigau, Kenya, regarding snakes and observational notes of teachers' interactions with live snakes. Further, the study explored the relationship between teachers and snakes and the teachers' change of perspective toward snakes during a three-month period after exposure to the workshops.

During the first three weeks prior to the first workshop, 100% of the teachers I spoke with (N = 60) were suspicious of why I would have an interest in snakes, as anyone who handles snakes in this area is believed to have *juju* (magic). Both principal participants confessed later that they thought my ability to handle snakes may have been enhanced by a talisman or some other metaphysical empowerment when viewed through their cultural lenses, however, each professed that magic does not really exists, when viewed as teachers using a scientific perspective (Jegede 1997). Before the workshops, most of the people I encountered in Kasigau, Kenya shared stories with me depicting snakes as bad, evil, unpleasant, or disgusting, while relating emotions of fear and hatred. The only exceptions were three out of the five medicine men I interviewed who did not view snakes as evil, "...but dangerous creatures that one could not take chances with." However, many teachers said that some types were *tazamika* (pleasant to look at). I was told many times that a snake could be attractive, but that did not make that particular snake any less deadly, and I witnessed villagers killing snakes while expressing apparent fear and hatred.

During initial interviews, 100% of the 60 teachers interviewed professed a fear of snakes and believed that all snakes were dangerous and capable of delivering a "poisonous" (venomous) bite. No one I spoke to, including the local high school biology teacher, differentiated between venomous, mildly venomous and nonvenomous snakes. One noticeable exception was the python, as six teachers (10%) expressed awareness that pythons were supposed to be "nonpoisonous," but all teachers agreed that pythons should still be feared and killed because they are capable of crushing a person to death and also preyed on livestock.

As a result of exposure to scientific perspectives, the two principal participants exhibited an amazing transformation; to a lesser extent, so did the other five primary participants. These teachers' ideas about snakes changed from complete negativity toward all snakes to respect, interest, and an increased understanding of the ecological role of snakes. Still, all the teachers expressed concern about having venomous snakes near their houses or in their *shambas* (family farms) and expressed their conviction that they would kill a Puff Adder (*Bitis arietans*) or other dangerous snake if they found it near areas they frequented or where children played. However, harmless snakes, for example the Brown House Snake (*Lamprophis fuliginosus*), were to be spared in order to eat the rodents that plagued villagers' homes and fields. Exit interviews and post workshop observations of teacher participants in classrooms indicated that the other Kasigau teachers' conceptions of snakes (N = 53) were also changed as a result of the herpetofauna institute. 98% showed an increased interest in snakes and exhibited an alternative perspective while teaching about snakes during subsequent science lessons observed by me in all six schools within the five villages surrounding Kasigau.

Several important factors contributed to the teachers' change in attitude towards snakes, including their newly acquired ability to differentiate between harmless and dangerous snakes, their ability to ask different questions about snakes, and their experiences with a modeled positive-appropriate response to nonvenomous snakes by both male and a female herpetologists. 98% of the participants said that knowing there were harmless snakes was the first step in allowing an alternative perspective to be considered and the ability to positively identify harmless versus venomous snakes

TABLE 1. Scientific (Family, genus, species), Kitaita (with translations), and English names for snake species indigenous to the Kasigau region.

Scientific name	Kitaita name	English name	EDS
Family: Typhlopidae			
Typhlops lineolatus	Ngomu = moves forwards and backwards	Lineolate Blind Snake	Y
Rhinotyphlops unitaeniatus	Ngomu = moves forwards and backwards	Yellow Striped Blind Snake	Y
Family: Leptotyphlopidae			
Leptotyphlops scutifrons	Ngomu = moves forwards and backwards	Peter's Worm Snake	Y
Family: Boidae			
Python natalensis	Are	African Rock Python	Y
Eryx colubrinus	Kivuvu = serpentine movement	Kenya Sand Boa	Y
Family: Colubridae			
Lamprophis fuliginosus	Mwawaya = shy	Brown House Snake	Y
Lycophidion capense		Cape Wolf Snake	Y
Mehelya capensis		Cape File Snake	N
Mehelya nyassae		Dwarf File Snake	N
Coluber smithii	Nguluku = red	Smith's Racer	Y
Prosymna stuhlmanni		East African Shovel Snout	N
Hemirhagerrhis kelleri	Zagho	Striped Bark Snake	Y
Hemirhagerrhis nototaenia		Bark Snake	N
Rhamphiophis rostratus†	Choka Ya Nganga Nganga = snake that resembles a guinea fowl	Rufous Beaked Snake	Y
Rhamphiophis rubropunctatus†	Nguluku = red	Red-spotted Beaked Snake	N
Psammophis sudanensis†	Zagho	Northern Striped-bellied Snake	Y
Psammophis mossambicus†	Zagho	Olive Sand Snake	Y
Psammophis punctulatus†	ndezi ya ng'ombe = walks among cattle	Specked Sand Snake	Y
Psammophis biseriatus†	Kisikiria Maza = listens to stories	Linked-marked Sand Snake	Y
Psammophis tansanicus†	Kisikiria Maza = listens to stories	Tanganyika Sand Snake	N
*Atractaspis microlepidota**		Small-scaled Burrowing Asp	Y
Aparallactus jacksoni†		Jackson's Centipede-eater	N
Aparallactus guentheri†		Black Centipede-eater	N
Aparallactus lunulatus†		Plumbeous Centipede-eater	N
Micrelaps boettgeri†		Desert Black-headed Snake	Y
Micrelaps bicoloratus†	Zagho	Two-coloured Snake	N
Meizodon semiornatus		Semi-ornate Snake	N
Philothamnus battersbyi	Ikumbo = green	Battersby's Green-snake	Y
Philothamnus punctatus	Ikumbo = green	Speckled Green-snake	Y
Philothamnus semivariegatus	Ikumbo = green	Spotted Bush Snake	Y
Dasypeltis medici	Nguluku = red (red phase only)	Rufous/East African Egg-eater	N
Dasypeltis scabra		Common/Rhombic Egg-eater	N
Crotaphopeltis hotamboeia		White-lipped Snake	N
Telescopus semiannulatus†	Nguluku = red (reddish or pink phases only)	Large-eyed Snake	N
*Dispholidus typus**	Vunjarere (green/black "kivuensis" phase) Bafwe (black phase)	Boomslang	N
*Thelotornis capensis**	Ifurudi	Savannah Vine Snake	Y
Family: Elapidae			
*Naja nigricollis**	Bafwe (black phase) Ilimanjighu = eats hyrax (brown phase)	Black-necked Spitting Cobra	N
*Naja pallida**	Nguluku = red	Red Spitting Cobra	Y
*Naja haje**		Egyptian Cobra	N
*Dendroaspis polylepis**	Ilimanjighu = eats hyrax	Black Mamba	Y
Family: Viperidae			
*Causus rhombeatus**	Kili = (from English "kills")	Rhombic Night Adder	N
*Bitis arietans**	Kili = (from English "kills")	Puff Adder	Y

The list presented is a synthesis from regional maps from Spawls et al. (2004) and the Taita Discovery Center's unpublished Reptile Checklist assembled by E. Selempo (2002). EDS = Encountered During Study: Y = Yes / N = No *Venomous snakes. †Mildly venomous snakes.

was a key component in forming their new perspectives toward snakes. This new attitude was also dependent on myriad other factors, such as teachers' views of science, trust in the facilitator, and pride within the community.

Educational experiences can have a significant impact on teachers' conceptions of snakes within the environmental/conservation education realm. The majority of previous studies involving human-snake relations have been attitude surveys using quantitative methodology (e.g., Kellert 1996; Öhman and Mineka 2003) or short-duration intervention, i.e., snake talks with brief exposure to live specimens (e.g. Morgan and Gramann 1989; Gomez et al. 2004). Although quantitative survey methods may be helpful in establishing baseline data and brief exposure interventions may afford short durational change in attitude, neither allow for an understanding of more complex conceptions of snakes nor the situational influence of human-snake interactions. Herzog and Burghardt (in Rowen 1988) suggested, "there are many important questions that can only be investigated by studying subjective reports of conscious experience, a position referred to as phenomenology" (p. 91). The current study emphasizes that peoples' conceptions of snakes are not just negative or positive. Teachers in this study exhibited complex reactions depending on the type of snake encountered, the situation and their own level of confidence and knowledge of snake identification. As part of qualitative research studies involving human-animal interactions, opportunities for teacher transformative learning can take place (Loucks-Horsley et al. 2003).

Having been an advocate of snake conservation education for the last twenty-five years, it was gratifying to witness the change in behavior of teachers who were once convinced that all snakes were dangerous and deserved to die and scoffed at the very idea of touching a snake. The teachers who held snakes during snake talks expressed how proud they were at having overcome their fear and were very pleased that they now had a new understanding of snakes. For them the phrase "a snake is a snake" was no longer true. Their traditional conception of "snake" had now been broadened by their willingness to participate in experiential opportunities involving live snakes and from taking the time to learn the important ecological niche of snakes. The teachers told me that now that they understood that some snakes were indeed harmless and important controllers of rodents, they would include snake conservation lessons in their classrooms and refrain from killing harmless species they could positively identify.

Another avenue for future research is the influence of gender on perspectives toward snakes within specific cultural settings. A study which explored the differing view of how males perceive females during snake interactions versus how females actually interact with snakes during snake encounters when men are not present would be an important contribution to the field of human-animal relations.

Conversely, I was also affected by my experiences in Kenya. Up until my trip to Kasigau I had never met anyone who had lost a loved one to snakebite nor had I met anyone who had lost a limb due to snake envenomation. Although I am still very adamant concerning the need for snake conservation, I am much more understanding of those who do not like snakes or have a desire to kill snakes. Kasigau has a rich diversity of snakes but, with so many dangerous species present, I have a newfound respect for those persons who would prefer to have nothing to do with snakes. During the short time I was living in the village of Bungule I witnessed much suffering due to snake encounters, for example, the 'three-legged' man who lived in Jora who was bitten by a Puff Adder on his calf and had to have the leg amputated above the knee because of the lack of antivenin, the Kasigau Subchief who had lost his daughter from the bite of a Black Mamba, and the ACK Minister whose sister died from a snakebite when he was a boy.

Lastly, it is imperative that we protect ecosystems, not just charismatic megafauna. The only hope for biodiversity is to conserve complete ecosystems and snakes play an important role in many such systems. Additional studies that integrate education, herpetology, and human-animal interactions are vital for the increased understanding of herpetofauna conservation efforts.

Acknowledgments.—Authorization to conduct this research was granted by the Kenyan Ministry of Education, Science and Technology and the Kent State University Human Subjects Review Board. I extend a heartfelt *chawucha* to the people of Kasigau, especially the teachers and administrators. I thank P. Malonza, J. Measey and B. Bwong, and C. Gakii Murungi for assistance during 2004 and 2005. I would also like to thank two anonymous reviewers for their comments on earlier drafts of this manuscript. In addition, I thank the Society for the Study of Amphibians and Reptiles and the Kent State University Center for International and Intercultural Education for funding support. However, the views and opinions in this document may not reflect the views of the funding agencies.

A frog chorus offers the opportunity for evaluating reproductive or territorial activity remotely, and sound pressure level (SPL) has been used to investigate the behavior and nocturnal activity of *Eleutherodactylus* frogs (Drewry 1970; Woolbright 1991; Stewart and Bishop 1994; Narins 1995; Woolbright et al. 2006). As data logging SPL meters have become prevalent, compact, and economical, overnight recording and analysis of SPL is readily accessible. The Coqui Frog chorus SPL exhibits distinct overnight patterning. We developed a piece-wise linear model of the overnight chorus SPL derived from recordings of *Eleutherodactylus coqui* in Hawaii. From this simple model, standardized parameters can be calculated that may be used to correlate frog behavior with environmental variables and to monitor frog populations.

Materials and Methods.—SPL was recorded with a Rion model NL-32 (IEC 61672-1 2002 Class 1) data logging meter. Equivalent continuous sound level, $L_{Aeq\ (1\ sec)}$ measurements were made at 1 sample per second in the A-frequency weighting mode. Each 1 second sample was averaged internally by the SPL meter at intervals of 20.8 μ sec. Bandpass filtering was targeted specifically for the *E. coqui* audio spectrum by using a Rion model NX-21VA universal filter card, configured as a third-order Butterworth bandpass filter. This filter offered discrete lower and upper cutoff frequencies selected at respectively 1 KHz and 3.15 KHz, bounding the Coqui audio emission spectrum. A Rion model EC-04A microphone extension cable, 5m in length, was used in conjunction with a waterproof enclosure to protect the SPL meter from weather. The microphone outfitted with a windscreen ball was mounted on a tripod at approximately 1.7 m above ground, simulating the typical height of the human ear. The tripod mounting was sheltered from rain and other elements by an umbrella suspended from an overhead line 0.5 m above the microphone. The SPL meter was calibrated prior to the start of recordings using a Rion model NC-74 Sound Calibrator (IEC 60942 1997 Class 1). The SPL meter was outfitted with higher capacity external batteries to maintain power requirements for continuous overnight recordings.

Concurrent with SPL measurements, audio recordings were also made using an RCA model RP5035A digital voice recorder in close proximity to the SPL microphone. Bandwidth and upper frequency limit was approximately 3 KHz. Data were stored in MP3 format running at Standard Play (SP), 16K bits per second. Audio recordings were utilized simply to identify and verify occurrences of man-made, meteorological, and other noise interference that may have occurred during SPL measurements. Examples include cars passing by, birds, dogs, wind, and rain. Identification of noise interference from the audio recordings validated selectively editing relatively short segments of SPL data when deemed necessary.

Overnight recordings of the male Coqui chorus were collected between approximately 1700 and 0800 h on Hawaii Island at various forested locations in the vicinity of Hilo (52 data sets) during August 2006–July 2007. SPL data sets were reduced by selecting samples at 2-sec intervals and twice applying a 15 min running average smoothing of the raw data. To facilitate accurate averaging of logarithmic data, raw SPL data (L_{raw}) were first exponentially transformed to raw sound pressure units (P_{raw}) by the formula:

$$P_{raw} = [10^{(L_{raw}/10)}]/10^6 \quad (1)$$

The constant factor 10^6 was used to scale down the otherwise relatively large numbers to preserve accuracy of computer calculations. The raw pressure data (P_{raw}) were then filtered twice using a time domain midpoint, 451 data points (i.e., a 15 minute), moving average smoother by the formula:

$$P_{smooth}(i) = {}_{1/451}\sum_{j=-225}^{+225} P_{raw}(j) \quad (2)$$

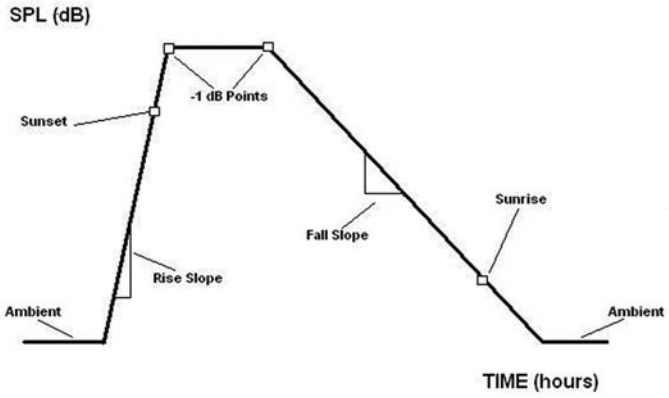

FIG. 1. Piece-wise linear model of the male *Eleutherodactylus coqui* overnight chorus. The parameters defining the model phases are indicated.

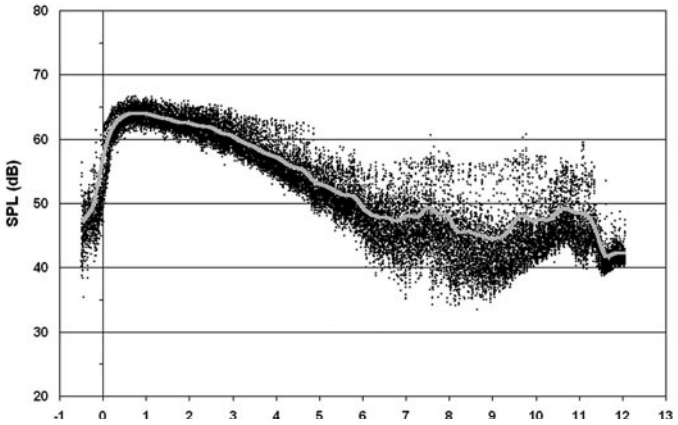

FIG. 2. Typical raw data overnight record of male Coqui frog chorus from Hawaii with moving average smoothed data trace superimposed. There were neither rainfall events contributing to the SPL nor any individual frogs very near the microphone to dominate the signal.

where i = ith data point (i.e., the j = 0 midpoint), and j = jth data point for summation.

Finally, twice-smoothed pressure data (P_{smooth}) were transformed back to smooth SPL data (L_{smooth}) by the formula:

$$L_{smooth} = 10 \text{ Log}_{10} [10^6 (P_{smooth})] \quad (3)$$

Data for this study were analyzed using Microsoft Excel 2002.

We represented the typical male Coqui overnight chorus as a piece-wise linear SPL model (Fig. 1). In addition to the expected ambient day time SPL just prior to sunset and soon after sunrise, the SPL model consists of the following characteristic phases:

Rise: a relatively rapid increase in SPL from a daytime ambient until a plateau is reached where male Coqui chorus is relatively constant (the time of sunset occurs during the rise phase).

Plateau: a period in time when the average SPL is fairly constant (the endpoints were chosen such that double-smoothed SPL data lie within -1 dB of the maximum double-smoothed SPL value).

Fall: a relatively slow decline in SPL from the plateau phase back down to ambient SPL (the time of sunrise occurs either near the end of the fall phase or during the ambient following the fall phase).

Ambient phases before sunset and after sunrise were not further analyzed in this study as these periods included only an occasional frog vocalization. The slope of the rise phase (dB/minute) was calculated using a first order least squares fit of the raw SPL data (L_{raw}). The period of interest was the most linear portion of the rise segment, typically starting approximately 10 minutes prior to sunset and terminating prior to the first -1 dB point (derived from the double smoothed SPL data L_{smooth}), which marks the start of the plateau phase.

The period or duration of the plateau phase was derived from the smooth SPL data (L_{smooth}). First, the maximum SPL was found, next the -1 dB points occurring prior to and following the maximum SPL were located. The difference in time between the two -1 dB points established the plateau phase width in units of hours. Other plateau parameters of interest were calculated from the raw SPL data (L_{raw}) defined in time by the previously established -1 dB points in the smooth SPL data, including L_{raw} (dB) mean and standard deviation. The slope of the fall phase (dB/minute) was calculated using a first order least squares fit of the raw SPL data. The period of interest was the most linear portion of the fall segment selected starting after the second -1 dB point from maximum obtained from the smooth SPL data and terminated when the raw SPL data reached ambient, or when noise interference as described above was encountered. Other model parameters of interest included the ratio of rise to fall slopes, the time in hours of maximum SPL and the first and second -1 dB points referenced to sunset and derived from the smooth SPL data.

TABLE 1. Parameter values of the piece-wise linear SPL model (Fig. 1) of the overnight chorus of *Eleutherodactylus coqui*. Data are values from N = 52 data sets recorded. For plateau converted P_{raw} SPL, statistics were derived in the sound pressure domain, then logarithmically converted to SPL dB (see Methods). For plateau maximum SPL and timing parameters, data were derived from moving average smoothed sound pressure domain data converted to SPl dB (L_{smooth}).

Model Parameter	Mean	Standard Deviation	Minimum	Maximum
Rise (dB/min)	0.379	0.212	0.073	1.020
Fall (dB/min)	-0.036	0.014	-0.081	-0.014
Ratio (rise/fall)	-11.20	6.03	-25.0	-1.80
Plateau Mean SPL (dB)	66.4	2.98	60.5	73.5
Plateau Maximum SPL (dB)	67.1	2.95	61.2	74.0
Plateau Timing Relative to Sunset of:				
1. Maximum SPL (h)	0.90	0.32	0.34	1.80
2. First -1 dB from maximum SPL (h)	0.44	0.24	0.11	1.07
3. Second -1 dB from maximum SPL (h)	1.65	0.48	0.54	2.68
Plateau Width (h)	1.23	0.49	0.23	2.18

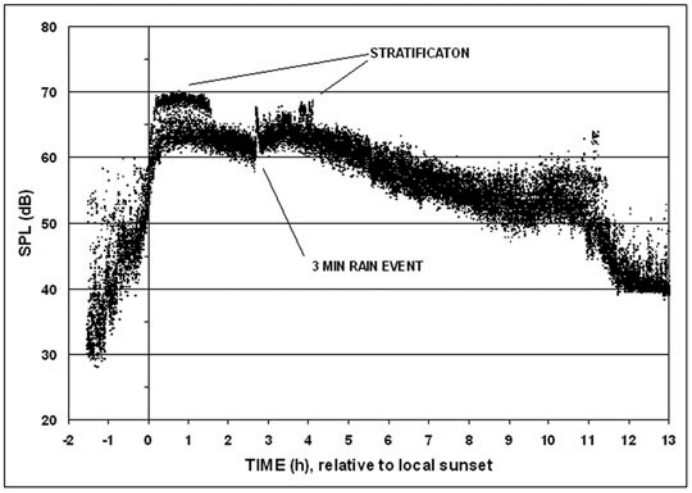

FIG. 3. A raw data overnight record of a Coqui chorus showing stratification episodes likely due to a calling frog positioned near the microphone. The spike-like elevation in the signal during the falling phase was a brief episode of heavy rain and was followed by elevation of the frog chorus SPL.

Results.—A typical overnight record of raw SPL data superimposed by its associated doubly-smoothed running average data set from shortly before sunset until sunrise is shown in Fig. 2. Model parameters calculated from the collected SPL data sets are shown in Table 1. The evening rising SPL chorus was typically more rapid than the late-night decline of the falling phase by a factor of approximately 11. The plateau phase started and ended on an average 0.44 h and 1.65 h after reference sunset, respectively. The plateau phase lasted an average of 1.23 h. We also observed some variable patterns in the SPL data. For example, during the early portion of the chorus rise phase, there were often scattered high level SPL data points appearing as outliers to the predominant upward trend (Figs. 2 and 3). After reviewing corresponding audio recordings during the same period, the phenomenon was found to be the result of one or two frogs initiating vocalization in relatively close proximity to the SPL instrument microphone. As the overall upward trend of SPL catches up, these points are absorbed into the composite SPL. Various other sources of sound were also identified, such as early evening vocalization of birds and distant barking dogs, passing cars, or overhead aircraft during the rise segment; however, most contributed only to the lower level background SPL. During the plateau phase, if one or more male Coqui call from sites very near the SPL microphone, the resultant SPL signal appears stratified as shown in Fig. 3. This source proximity effect was also occasionally observed during the late night falling phase of data sets.

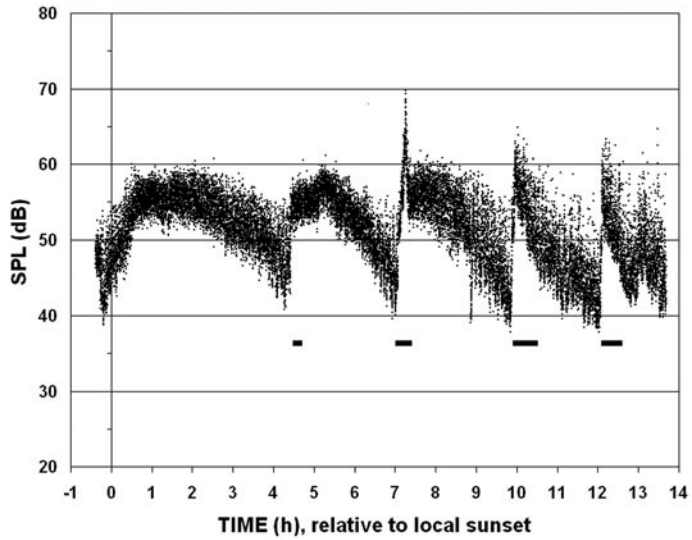

FIG. 4. A raw data record of a Coqui chorus involving several successive heavy rainfall events during the falling chorus phase. The horizontal bars show the timing of rainfall.

Rain, especially brief heavy downpours, was manifested in the SPL data as a sudden spike-like increase in SPL followed by a slower decrease as the rain subsided (Fig. 3). Of the 52 SPL data sets analyzed, over 50% contained one or more heavy rain events as revealed by the corresponding audio recordings. After the SPL spike due to rain subsided, the SPL due to male Coqui vocalization appeared several dB higher compared to the SPL prior to the associated rain event (Fig. 3). In addition to heavy episodes of rain, light to moderate rain events occurred in approximately 15% of the 52 data sets analyzed. In these cases, the onset of rain was not distinguished from the subsequent male Coqui chorus as a spike in SPL, however, concurrent audio recording verified presence of rain, along with a corresponding rise in SPL (Fig. 4). When multiple rain events occurred late at night, the result was a saw-tooth-like pattern of SPL as the generally declining male Coqui chorus level was successively re-elevated, apparently stimulated by the occurrence of each new rain shower (Fig. 4).

Discussion.—SPL recordings of the male Coqui chorus show temporal events that are useful for understanding the behavior and activity of the frogs, as well as for monitoring their recent colonization of the Hawaiian Islands. From the SPL model (Fig. 1), the plateau phase affords the best opportunity for researchers to study Coqui behavior that is consistent with the highest level of activity as indicated by male Coqui vocalization during a given night. SPL data reduction to 1 sample every 2 seconds was more than adequate to provide useful analyses of pattern characteristics of male Coqui SPL. The two-pass moving average smoothing filter applied directly to the raw pressure domain data is widely considered as one of the most optimum data analysis techniques for use on temporal data (Smith 2003). A smoothing parameter of 15 minutes was selected as a tradeoff to account for both slow-moving trends during the rise and fall phases of the SPL data and the relatively fast changing transition from the rise to the plateau phases of the SPL. In addition to plateau mean SPL, the slopes of the rise and fall phases and their ratio may serve as another measure of the intensity of reproductive activity of a frog population. Steeper rise slopes are expected from more rapid emergence and recruitment of males to the chorus after sunset, and shallower (less negative) fall phase slopes may represent individual frogs extending calling activity or additional frogs recruited to the chorus later at night.

Coqui frogs behaviorally reduce signal interference with near neighbors by patterning their vocalizations to avoid overlap in time and space (Brush and Narins 1989; Narins 1983; Stewart and Bishop 1994). These behaviors tend to stabilize the temporal, spatial, and frequency variation of the chorus. However, if one or more frogs perch very close to the microphone, their individual

calls will dominate the SPL signal producing the stratification observed in Fig. 3, and this proximity effect is an important consideration for microphone placement. Assuming a homogeneous spatial distribution of male Coqui, the SPL meter should be strategically positioned near the centroid of a typical frog density cell. An on-site observer with a hand-held SPL meter can avoid recording from positions with nearby calling frogs and make multiple recordings from several positions. For remote longer-term recording, a position should be selected with no immediate adjacent vegetation that offers perch sites to recruit calling frogs near the microphone.

Other important sources of variation in the pattern of frog SPL are temperature and rainfall. Temperature is well known to affect calling behavior of frogs including *E. coqui* (Drewry 1970; Drewry and Rand 1983). We observed a strong influence of brief rain showers that subsequently raised frog SPL within a single night of recording (Figs. 3 and 4). Penna et al. (2005) observed increases in call rate and duration of individual *Eusophus calcaratus* (Leptodactylidae) frogs during exposure to natural and synthetic rain, wind, creek, and sea surf noise. This evoked response could be a mechanism of coping with potential vocal signal interference, however the *E. coqui* chorus SPL response to rain continued to build following brief rain events occurring up to 7 h after sunset (Figs. 3 and 4). Rainfall during the night as well as the immediate past history of rainfall influences the availability of liquid water in the habitat. These factors affect frog evaporative water loss and potential for re-hydration by water uptake across the skin. In turn, they influence the time frogs can be active abroad. In the present study, it is not clear whether rain events wetting the vegetation and floor of the forest during the night stimulated recruitment of additional new frogs to the chorus or stimulated formerly calling frogs to resume calling activity.

While more dense populations of calling frogs are expected to be louder, Drewry (1970) showed in a theoretical model of *E. coqui* sound fields that the relationship between overall SPL and frog density is non-linear. At relatively high calling densities with SPL > 60 dB, the male Coqui chorus SPL is expected to exhibit an increasing, yet asymptotic upper bounded trend in SPL as calling frog density is increased. Based on the model and data presented here, auto recording of SPL from approximately 0.5 h–1.5 h after sunset with selection of the most level or plateau portion of the data segment for averaging, is the best time to characterize the maximum levels of the nighttime vocalization of *E. coqui*.

Biological disciplines such as palaeontology and comparative anatomy have long embraced computed tomography (CT) as a non-intrusive way of visualizing bone (Conroy and Vannier 1984; for an extensive CT-scan database visit http://www.digimorph.org/index.phtml). However, most of these studies are conducted on large specimens using low-resolution medical CT scanners, or on expensive specialized scanners accessible to few researchers. However, "general purpose" micro-CT scanners are increasingly common (Holdsworth and Thornton 2002; Kalender 2006) and can be accessed, for reasonable fees or through collaborations, in hospitals or university departments that own scanners. In addition, easy-to-operate sophisticated reconstruction programs, some of them free of charge, exist. Micro-CT allows determination of existence, shape and structure of mineralized tissue; it is non-intrusive, fast, reproducible and can provide images of microscopic detail. As such, micro-CT has significant advantages over destructive techniques such as clear-staining or maceration and does not require

specialized laboratory equipment. This is particularly useful for herpetological research, which frequently targets ossifications in small specimens. Micro-CT has already been successfully applied in herpetological studies of ontogeny (e.g., Boughner et al. 2007) and comparative skeletal morphology (e.g., Kley 2006; Maisano et al. 2001) but would also be useful for assessing phylogenetically relevant osteological information (e.g., Nuin and do Val 2005). Nevertheless, this technique remains little utilized by the broader herpetological community. This may be because the accessibility of Micro-CT scanners is not widely perceived, and usage of the equipment and reconstruction requires a certain degree of procedural expertise. The following is a short introduction to micro-CT with an overview over the most important procedures and parameter settings for CT scanning of small vertebrate specimens.

To scan a specimen, it is placed between an X-ray source and a radiation detector. The source exposes the specimen to X-rays at a specified voltage and current and for a given exposure time. Most micro-CT scanners are cone-beam scanners which return a projection image of the rays attenuated by the specimen as a two-dimensional image, with increasing darkness (or lightness, if projection image "negatives" are preferably viewed) signifying increasing density (Fig. 1); however, fan-beam scanners return so-called sinograms that contain all information but are not directly interpretable. A simple evaluation of some projection images can provide all information needed within minutes (e.g., presence and approximate shape of a bone; Fig. 1), which makes this a very fast and inexpensive process. For full image acquisition to enable 2D-slice reconstruction and 3D-modelling, the specimen or the source/detector system (depending on the scanner) is rotated by a specified small angle and the next image is acquired, until images of the specimen have been taken throughout at least 180° (360° rotation yields larger datasets but also provides better reconstruction quality).

Maximum micro-CT resolutions are constantly increasing and vary depending on the scanner and detector model used. Resolutions of up to 3 μm are possible (some "Nano-CT scanners" also work at a nanometer-scales). However, since resolution is inversely related to specimen size, such resolutions are generally only achieved at very high magnifications (usually above 100x) and with pin-head-sized specimens. Magnification and resolution for visualizing whole specimens will typically be upwards of 10 μm. Maximum scannable specimen size also depends on scanner characteristics and varies from 30 mm to human head size. It is constrained by specimen impedance (large specimens may be too dense for the radiation to penetrate), chamber volume, and source distance (as the source approaches the specimen with increasing magnification, there is a danger of the two colliding). Magnification can be increased to scan only specific components within a specimen (Fig. 1 inset).

For full acquisition of wet specimens, retention of moisture must be ensured using wrapping materials with as little impedance as possible (Fig. 2). Non-PVC food wrapping film and stretching lab tape (e.g., parafilm; Fig. 2) are excellent wrapping materials because they keep specimens moist and have low impedance (faint shadows produced by plastic film can be seen in Fig. 1 inset). For obtaining clear specimen outlines, specimens can be placed in oil to increase the density contrast between the specimen and the surrounds (Boyde et al. 2000), but this may not be an option for museum specimens. Immobilization of the specimens is crucial because even slight movement during scanning precludes the reconstruction of cross-sectional slices. Delicate specimens can be fixed in a narrow cleft cut into a cube of radio-translucent material such as styrofoam (a faint styrofoam shadow can be seen in the lower half of Fig. 1), which is attached to the mounting surface using tape (double-sided tape is very useful) or plasticine. It is also common to slot specimens into blocks of agarose gel (Claeson et al. 2007), and simple plastic vials attached to the mount using plasticine are also useful

Fig. 1. Projection image of *Choerophryne rostellifer* (South Australian Museum A3779) taken on a SkyScan 1072 micro-CT scanner at 80 kV, 100μA, and 2.9 s exposure time, frame averaged over two images. Scale bar: 3 mm. Inset: Detail of the wrist of the same specimen at increased magnification. The line across indicates the position of the slice reconstructions in Fig. 3.

For slice reconstruction and 3D modelling, the structure to be reconstructed must be fully in camera view at all angles of rotation. To prevent the specimen from going out of view, and to reach optimum magnification, the specimen should be positioned exactly in the centre of rotation. If possible, it is advisable to preview projection images at various angles to ensure proper positioning of the specimen.

Most acquisition parameters involve modifying the x-ray spectrum to suit the attenuation properties of the specimen scanned. High voltage increases x-ray penetration and is suited for dense objects such as fossils or dense bone. In small wet specimens or if bone is thin, voltage reduction and current increase, if possible, can yield better distinction of soft tissue features (Kalender 2005). Metal filters (e.g., aluminium or copper) modify the energy spec-

FIG. 2. Some wrapping materials (single or double-sided sticky tape, plasticine, plastic vial) and an example of an arrangement for fixing delicate specimens and retaining its moisture (bottom left). The specimen (not shown) is slotted into a styrofoam cleft and parafilm is folded around it. Note that the fold on the right side of the cube should not be too thick to avoid interference with the 2D reconstruction quality.

trum emitted and are commonly applied to reduce noise in dense materials such as fossils or rock (Kalender 2006; Ketcham and Carlson 2001). Exposure time, if not optimized automatically, is also an important parameter. It should be set for good contrast between background and bone, but if parts of the projection image are purely white or black, some grey values are beyond the signal perception limits of the detector, which results in loss of image information (Kalender 2005). Frame averaging reduces noise by acquiring and averaging several projection images at the same angle, thereby providing clearer images.

Acquisition time and dataset size depend on rotation angle per acquisition, frames averaged, and exposure time. In all cases, the faster or less memory-demanding option is traded off for lower resolution or image quality.

Reconstruction of 2D "slices" perpendicular to the axis of rotation is achieved by an algorithm which processes the projection images previously taken (Fig. 2; e.g., Kalender 2006; Zollikofer and Ponce de Leon 2005). Slice reconstruction software is generally available at the scanning facilities and slice reconstructions are sometimes provided. If reconstruction needs to be done separately, some settings need to be considered optimum image quality. This involves adjusting the settings to ensure that the slices are not misaligned, which can occur through slight movement of the specimen during the scan; typical symptoms of misalignment include "tails" (Fig. 2B), double lines, and blurry images. Artifacts such as beam hardening (where the outer areas of the object appear to

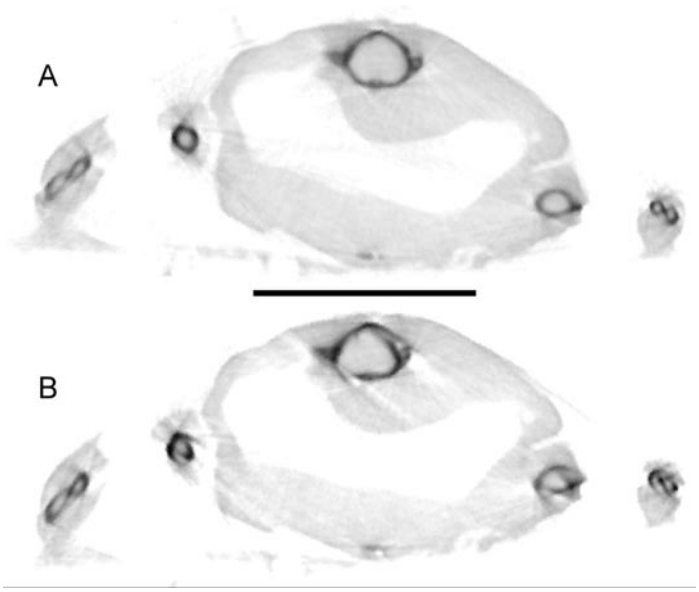

FIG. 3. 2D slice reconstructions of *Choerophryne rostellifer*, taken at 80 kV, 100μA, and 2.9 s, 0.23°rotation per acquisition, frame averaged over two images. A, Optimally reconstructed slice; B, Badly aligned reconstruction. The arrow points out the "tails" typical for a misaligned 180° reconstruction. Scale bar: 3 mm.

be denser) and ring artifacts (where concentric rings occur in the image) can also be remediated to some degree by the reconstruction algorithms. Reconstruction times and sizes vary depending on how many slices are reconstructed and how fine the angle of rotation was. Dataset sizes of 1 GB upwards are common. Slice reconstructions are generally in a common image file format which can be viewed conveniently by programs that allow the playing of the images as a movie (a useful free program is DataViewer, which also allows measuring distances in 3D; Sasov 2007). However, often the reconstruction software returns so-called DICOM images, which are viewable with special DICOM viewers (e.g., the freeware DicomWorks; Puech and Boussel 2008); the free image viewing program IrfanView (Skiljan 2007) also allows batch-conversion of DICOM files into more common image files.

There is a range of possible applications for 2D slices, including tissue density determination, morphometrics, volumetrics, or discrimination of trabecular vs. cortical bone (for more details, see Kalender, 2005; Zollikofer and Ponce de Leon, 2005). The most popular application for visualization of 2D slices is 3D reconstruction. This is achieved by thresholding out that portion of grey values in the 2D slices which correspond to the density of the elements to be reconstructed. The 3D reconstruction can also be restricted to a particular region of interest (ROI). All image components within the chosen grey values are then "stacked together" by the reconstruction algorithm to yield a three-dimensional structure. Note that morphometric measurements of three-dimensional objects are influenced by the threshold chosen, which can lead to inconsistent measurements (Coleman and Colbert 2007). Sophisticated three-dimensional reconstruction programs are often available with the processing software at scanning facilities (e.g., Disect, VGStudioMax, Amira, Mimics). However, reconstructions can be made using freely downloadable 3D-reconstruction programs (e.g., ImageJ, Abramoff et al. 2004; Drishti, Limaye 2006) on any computer with enough memory. The reconstruction in Fig. 3 was

FIG. 4. Ventral view of a 3D reconstruction of a scan of *Oreophryne brevirostris (*South Australian Museum A8589) using Drishti. Scale bar: 3 mm.

made with Drishti (Limaye, 2006). The quality of 3D reconstructions depends on the quality of the 2D slices and the graphical rendering capabilities of the reconstruction program used. However, considerable computer and graphics card memory are required in order for the programs to run at sufficient speed.

The limitation of CT for biological specimens is that it only differentiates bone, water, air, and fat (e.g., Ritman 2002). "Desktop" cone-beam micro-CT scanners in particular do not show non-mineralized tissue elements very well (Kalender, 2005). A number of approaches using stains for discrimination between various tissues are rapidly being developed (e.g., Palmer et al. 2006; Ritman 2004; Uzun et al. 2006), but these can only be used on destructible specimens. Since the field of high-resolution CT scanning is still developing rapidly, scanner capabilities regarding specimen size, resolution, or magnification are continuously being improved so that considerable improvement to this already fast and effective method can be expected within the next few years.

Acknowledgments.—We thank A. Sasov and Nick Corps for advice and access to software, and Ajay Limaye for his help with Drishti. We thank A. Jones, M. Sánchez-Villagra, M. Archer, and T. Playford for discussion. SR is grateful to the South Australian Museum and Conservation International for their considerable support of this research program. Siren spp. and *Amphiuma* spp. are large eel-like salamanders distributed throughout the coastal plain of the southeastern United States (Conant and Collins 1998). Much has been reported on capture methods for these species. Common methods include minnow and crayfish traps (Sorensen 2004), hoop nets (Snodgrass et al. 1999), dip nets (Fauth and Resetarits 1991), and baited hooks (Hanlin 1978). Recently, a trap capable of sampling these species at depths up to 70 cm was developed (Luhring and Jennison 2008). Because of their slippery skin and irritable nature, *Siren* spp. and *Amphiuma* spp. are difficult to handle. Little has been published on methods to aid in field-handling of these species. Sorensen (2004) used a modified squeeze box to restrain individuals (Cross 2000). Luhring (2005) restrained individuals by wrapping them in a damp cloth. Frese et al. (2003) anesthetized individuals prior to marking and measuring.

We found snake restraining tubes (King and Duvall 1984) to be a safe and effective device for restraining *Siren texana* (Dixon 2000) in the field (Fig. 1). The set we used included nine clear plastic tubes obtained from Forestry Suppliers Inc. (Jackson, Mississippi), measuring 609.6 mm in length and ranging in diameter from 9.5 to 50.8 mm. This allowed all *S. texana* encountered (N = 31), ranging from 84 to 443 mm snout–vent length, to be restrained effectively. An opening at each end of the tube allowed constant airflow to be maintained, and water was trapped in the tube with the *S. texana* which prevented desiccation.

Captured individuals were initially placed in holding bags so that they could be manipulated into entering the tubes. However, we found it more efficient to house the *S. texana* in a large cooler containing enough pond water to cover their bodies prior to handling. Individual *S. texana* were easily disturbed by touch and swam directly into tubes placed in the water in front of them when disturbed. This allowed us to minimize contact with *S. texana*, decreasing the potential for handling injuries to both salamander and worker. Typically, a large individual would attempt to back out of the tube when it was between one third and half way in. In such cases, we held the tube vertical to the ground, with the posterior end of the *S. texana* facing up, and pushed the body into the tube until only the tail was free. The individual was then less able to move within the tube, facilitating accurate measurements, tail-clips, and photographs. *S. texana* were ejected from the tubes directly into damp perforated laundry sacks to be weighed by holding the tubes vertically, with the anterior portion of the individuals facing up, and pulling lightly on the tail.

We found that a single person could restrain and obtain all necessary data on a given individual in under ten minutes. A potential drawback of this method is that the salamanders will never be perfectly linear due to the necessity of having enough space to facilitate movement into the tube. However, once an individual is placed in a given tube, a smaller tube can be inserted at the anterior end and the salamander can be coerced into it by touching its tail, resulting in a tighter fit and more accurate measurements. The handling method we used was effective for collecting standard data and facilitating tail-clips. This method may not be useful when extremely accurate measurements are required or when investigating some morphological characters, such as bite-marks (Fontenot and Seigel 2008; Godley 1983). However, the tubes may be useful for restraining individuals prior to administering anesthetic vapor.

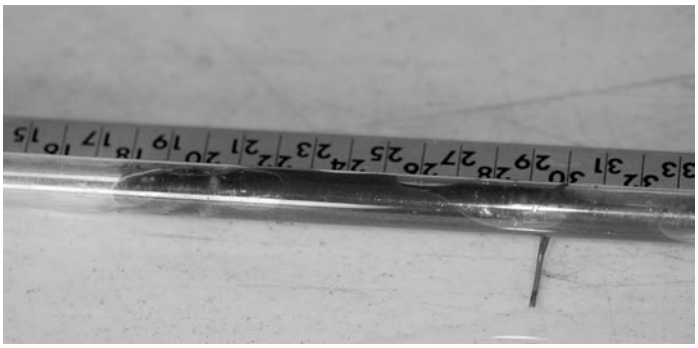

FIG. 1. *Siren texana* being restrained for measurements using a snake tube.

Acknowledgments.—We thank Maxwell Pons, Jr. and The Nature Conservancy of Texas for allowing us to trap herpetofauna at Southmost Preserve. Thanks to James R. Dixon, John Duvall-Jisha, and Josie Duvall for their trapping and handling assistance. Meredith J. Mahoney, Thomas M. Luhring, William Barichivich, and one anonymous reviewer provided useful comments on the manuscript. Individuals and funding were through the Texas Parks and Wildlife Department (Permit No. SPR-0102-191). This research was approved by the Texas State University-San Marcos Institutional Animal Care and Use Committee (Protocol No. 0715-0428-07).

Mark-recapture models used in estimating population size require the capture, marking, and recapturing of marked animals (Donnelly and Guyer 1994). Although several methods are available for marking amphibians (see Ferner 1979), sirenids and Greater Siren (*Siren lacertina*), in particular, present several problems for marking schemes. Sirenids have fewer total toes (6 or 8) than most salamanders and this limits the applicability of toe clipping schemes. Additionally, the dark skin of Greater Sirens prevents marks made by tattooing and injectable dyes from being easily read (Sorensen 2003). The only known test of multiple marking techniques on *S. lacertina* was conducted on two captive animals (Sorensen 2003). The marking techniques used on the two captive animals included cyano-acrylic, tail-notching, heat-branding and Passive Integrated Transponders (PIT tags). Of these, only PIT tags were successful in creating a lasting mark and were later used in field studies. While it was not deemed applicable for Greater Siren, previous studies on Lesser Siren (*Siren intermedia*) used heat branding to create marks that lasted for up to 96 months (Frese 2000; Gehlbach and Kennedy 1978; Raymond 1991).

The required level of identity (e.g., individual, cohort) and persistence (e.g., permanent, month, day) for a mark is dependent on the specific goals of a mark-recapture study. I tested two types of non-individual-specific marks on *S. lacertina* in an isolated herbaceous bay wetland to determine their permanence and readability. Passive integrated transponder (PIT) tags are effective at providing a permanent individual mark in *S. lacertina* (Crabill 2007; Sorensen 2003). Their proven persistence as a mark for *S. lacertina* allowed me to use them as a redundant mark to test other marking techniques used in this study.

There are several individual marking schemes for toe clipping amphibians (see Donnelly et al. 1994). However the utility of toe clipping for individually marking *Siren* is fairly limited as they only have eight total toes (most toe-clipping schemes are designed for amphibians with 18 total toes). For this reason, toe-clipping in this study was considered to be a cohort mark (i.e., different toe-clip combinations can be used in order to separate animals into smaller groups by a pre-defined criterion such as period of capture). Tail notching has been successfully used as a marking technique for larval anurans (Turner 1960). Sirens often have minor damage to their tailfins that can resemble a tail notch (pers. obs.). To avoid confusion with naturally occurring tailfin damage, I used an elongate arc or "tail scoop" (see Luhring 2008) as a tailfin mark on each marked animal. Because there is not an effective way to vary the appearance of a tail scoop, this method was considered to be a non-specific capture mark.

Methods and Materials.— All animals were captured from September 2006 to September 2007 as part of an on-going study on greater siren and two-toed amphiuma at Dry Bay, a 5-ha fishless Carolina bay located on the Department of Energy's Savannah River Site in Aiken County, South Carolina, USA (Luhring 2008). A sampling period occurred each month for ten consecutive days (for a total of 130 nights of trapping over 13 months) with a fyke net, and multiple arrays of hoop nets, trashcan traps (Luhring and Jennison 2008; Luhring, *in press*), and plastic and steel minnow traps (see Luhring 2008 for details of trapping design). Upon return to the laboratory, animals were weighed to the nearest 0.1 g on a Mettler PC 440 electronic scale (Mettler Instrument Corporation, Hightstown, New Jersey), measured on a meter stick for snout–vent length (SVL) and total length to the nearest 1.0 mm, and were then marked. Animals were photographed with a Nikon D70 (model# 25218) or Nikon D200 (model# 25235) camera with a Nikon 18–70 mm f/3.5-4.5G ED IF AF-S DX Nikkor Zoom Lens (model#2149) mounted on a Bogen TC-2 copy stand (Bogen Imaging Incorporated, Ramsey, New Jersey) to document mark regeneration and for later use in morphometric measurements. Animals were restrained for marking by placing them on a wet cloth. The cloth was folded over the animal's head and then the side of the cloth was folded over the animal. The animal and cloth were then rolled together to the opposite end of the cloth (see Luhring 2008). This technique of restraining the siren permitted access to the area immediately posterior to the vent for injecting a PIT tag (AVID Marketing, Incorporated, Norco, California) and administering a tail scoop while restraining the siren. Sirens did not need to be restrained for toe-clipping as they typically did not react to this type of mark. Larger sirens (>300 mm SVL) also typically did not react to receiving a PIT tag, however, all animals were restrained in the cloth for PIT tagging and tail scooping.

All PIT tags were injected towards the distal end into the ventral side of the tail 1–3 cm posterior to the vent. This is the same area used by Sorensen (2003); however, I injected the PIT tag ventrally as the ventral aspect at this point was wider and doing so negated having to avoid the spinal column. Tail scoops were made with dissection scissors on the dorsal side of the tail fin. The scoop usually started at the widest part of the tail fin and was cut ~5–7mm deep in larger animals (>400mm SVL) and 2–5mm deep in smaller animals (<400mm SVL). The general rule of thumb in deciding tail scoop depth was that no cut should be deeper than a quarter of the tail depth (i.e., halfway to the middle of the tail). Tail tissue was easier

to cut if making an initial cut at a 60–90° angle and then cutting towards the distal end of the tail in a shallow arc for 25–35mm (variable with body size of animal). Tissue from tail scoops was saved for genetic analysis and thus scissors were cleaned with a 10% bleach solution (to degrade any remnant DNA), run under tap water (to wash off any bleach), and then submerged in 70% isopropyl alcohol between the marking of each animal. Syringe needles were stored in 70% isopropyl alcohol prior to being used on PIT tag applicators. All PIT tag applicators and needles were wiped with a paper towel (to remove tissue residue) and 70% isopropyl alcohol between animals to minimize cross-contamination.

Markings on recaptured animals were given a four-stage rating based on a combination of photographic records and notes taken during laboratory measurements. Toe clips and tail scoops were given a 1 if they were freshly clipped and did not show any evidence of regrowth. They were given a 2 if there was only minor regrowth. A toe clip was given a 3 if it was partially re-grown (more than half the original size but less than ¾ the size of a full grown toe). Tail scoops were given a 3 if the tissue had healed and the site of the mark was obviously discolored. Toes and tails that were fully regenerated were given a rating of 4. If a mark was considered to be borderline between categories, it was given the higher numerical rating to provide a conservative estimate of mark retention (for photos of marks at different stages, see Luhring 2008).

Toe clips were taken from the siren's second innermost toe (the longest toe) on the right foot by using a pair of sharp scissors to cut the toe at the base where it meets the hand. A few animals had deformities (not associated with toe-clipping) on their designated hand, in which case a toe was taken from the left hand. While toe clipping was administered from the beginning of the experiment, tail scooping was initiated in January of 2007 at which time all animals received a toe-clip, a tail scoop and a PIT tag. Animals recaptured within the same ten-day trapping period were recorded and released at the site of capture without taking additional measurements.

Mark ratings were tested for significant correlations to the age of the mark, and changes in SVL, total length, and mass since the original mark. Regressions were tested with an analysis of variance (ANOVA) with a lack-of-fit test. Statistical analyses were run in Statgraphics (Centurion XV Version 15.2.06.).

Results.—A total of 102 recaptures of 72 toe-clipped animals and 94 recaptures of 58 tail scooped animals were analyzed for mark durability and readability. These data were grouped into 30-day intervals to represent monthly sampling efforts (Table 1). Days between captures ranged from 20 to 332 days for toe clips (100.2 ± 65.5 SD) and tail scoops (92.1 ± 57.3 SD). Most marks began showing signs of regeneration at around 30 days (Figs. 1, 2). Toe clips remained fresh or had only minor regeneration three times longer than tail scoops (61–90 days versus 20–30 days). Marks were readable (i.e., classified as a 1, 2, or 3) 180 days after they were given, however this is at the uppermost bound of tail scoop readability. The first observed loss of mark for a toe clip occurred 127 days after being administered. The first observed loss of mark for a tail scoop occurred 61 days after being administered. While the majority of toe clips were still readable within the 332 day maximum between captures (both recorded marks over 300 days were ranked as 3's) and one mark was a 1 at 216 days, most tail scoops were unreadable beyond 180 days.

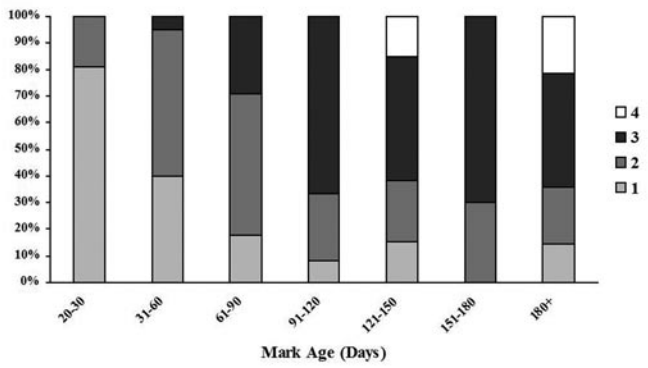

FIG. 1. Proportion of toe clip ratings by mark age of recaptured animals. 1 = fresh, 2 = minor regeneration, 3 = partial regeneration, 4 = loss of mark.

Toe clip and tail scoop mark readability were correlated to mark age, and change in SVL, TL, and mass ($p<0.05$). While tail scoop regeneration was best explained by mark age ($F_{1,87} = 144.59$, $p<0.0001$, $r^2 = 0.79$), toe clip regeneration was explained slightly better by change in SVL ($F_{1,98} = 96.15$, $p<0.0001$, $r^2 = 0.70$) than by mark age ($F_{1,98} = 89.65$, $p<0.0001$, $r^2 = 0.69$; see Luhring 2008 for complete ANOVA tables). A Fisher's least significant difference (LSD) test was used to compare the mean mark age (days) to mark rating (1–4) within toe clips and tail scoops and between toe clips and tail scoops (Table 2). Two outliers were removed from the toe clip statistical analyses to create a better fit for the model without affecting significance. The outliers belonged to the same animal that did not regenerate any toe tissue after 194 and 216 days. One outlier was removed from the tail scoop analyses for similar reasons (no tail tissue regeneration in 63 days) and did not affect significance. All three outliers are included in non-statistical figures and tables (Figs. 1, 2; Tables 1, 2).

Discussion.—Toe clips lasted longer than tail scoops and can also be used to create a finer level of distinction between groups

TABLE 1. Breakdown of toe clip (c) and tail scoop (s) mark readability (1–4) by mark age (days) for recaptured animals.

Readability	Mark Age 20–30 C	S	31–60 C	S	61–90 C	S	91–120 C	S	121–150 C	S	151–180 C	S	180+ C	S
1	13	4	8	0	3	1	1	0	2	0	0	0	2	0
2	3	11	11	5	9	2	3	0	3	0	3	0	3	0
3	0	1	1	13	5	10	8	10	6	7	7	5	6	1
4	0	0	0	0	0	3	0	2	2	3	0	4	3	9
Total	16	16	20	18	17	16	12	12	13	10	10	9	14	10

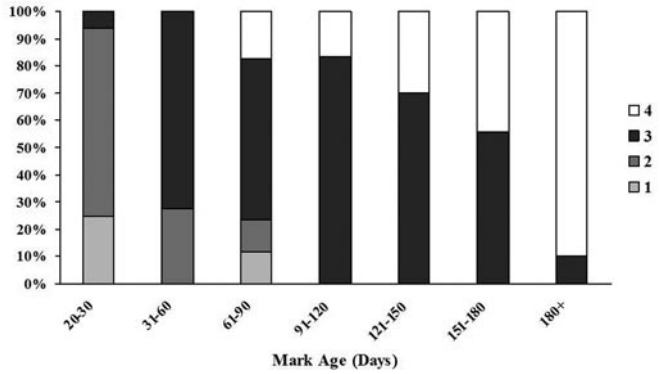

FIG. 2. Proportion of tail scoop ratings by mark age of recaptured animals. 1 = fresh, 2 = minor regeneration, 3 = partial regeneration, 4 = loss of mark.

of animals (cohorts). Most toe clips were still readable through the end of the study and one animal that was caught outside of the study period on 31 January 2008 had a readable toe clip that was 353 days old. Although there were five "lost marks" (a rating of 4) of toe clips, most of these were actually still distinguishable marks that surpassed the ¾ of original length threshold between a rating of 3 and 4. However, they were not easy to distinguish and may have only been distinguishable to someone familiar with what that specific toe should look like.

Toe clips would be best suited for mark-recapture studies lasting for a field season (January to September) and provide an opportunity for a cohort marking scheme. Toe clipping may also be used in conjunction with studies on skeletochronology (Bruce and Castanet 2006; Halliday and Verrell 1988) or for any studies needing tissue samples. The number of toes on *S. lacertina* (8) limits toe-clipping schemes. Additionally, I caution against removing multiple toes on the same foot because *S. lacertina* use their feet as much, if not more than, their tail (Schalk and Luhring, unpubl. data) to pull themselves through the water, vegetation, and organic debris, and the extent to which the loss of multiple toes would impact their survival is not known.

Although one tail scoop was readable 332 days later, 11 out of the 12 tail scoop marks that were over 165 days old were completely regenerated and no longer visible. After 63 days, all tail scoops were healed and only discolored tissue (a rating of 3) in the area of the original mark distinguished these animals as having been given a tail scoop. Of all the techniques tested, tail scoops might have had the shortest-lived effects on sirens. Tail scoops would be ideal for marking efforts that last for a short period of time (<60 days) and do not require a specific mark. The tissue taken from tail scoops is sufficient for quality DNA extraction (pers. obs.) and the rapidity of tailfin regeneration suggests that there are not any likely long-term effects of tail scoops. While mark age, and change in SVL, TL, and mass were significantly correlated to the quality of marks, these correlations were not directly tested for causation of mark regeneration. Future studies that test mark regeneration as it relates to the growth rates of aquatic salamanders may show differences for regeneration rates of different types of tissue. Greater Sirens show a reduced growth rate upon reaching a length of 400 mm SVL (Luhring 2008), and toe regeneration may be retarded in these animals (pers. obs.).

TABLE 2. Results of a 95% Least Significant Difference (LSD) test on the mean ages of mark type readability. Letters in homogenous groups column denote significantly different groups.

Mark Type-Readability	No. Ind.	Mean Age	Homogeneous Groups
Tail Scoop-1	4	25.0	A
Tail Scoop-2	18	35.5	A
Toe Clip-1	27	47.0741	A
Toe Clip-2	35	87.1429	B
Tail Scoop-3	47	94.2553	B
Toe Clip-3	33	143.242	C
Tail Scoop-4	21	160.095	CD
Toe Clip-4	5	193.6	D

There are still several other types of marking techniques available for testing on sirens and other permanently aquatic salamanders (e.g., visible implant alpha-numeric tags). While PIT tags work well for permanent individual identification, they cannot be used in larva and small juveniles of *S. lacertina* because of the large gauge needle needed to insert the tag into the tail (Sorensen 2003; pers. obs.). The golden flecking on *S. lacertina* is highly variable in respect to the amount present, as well as the shapes and sizes of individual flecks. This variation is possibly unique and might be useable for individual identification with photo-identification programs (see Gamble et al. 2008).

Until the validity of other such techniques are tested on *S. lacertina* in the field, I suggest using PIT tags for long-term studies or those requiring individual identification and either toe clipping or tail scooping for short-term studies not requiring individual identification. The use of a PIT tag as a permanent individual-specific mark was essential for determining the applicability of non-individual-specific marking techniques in the field. Field-testing marking techniques would presumably be the best indicator of how well those techniques would work in the field on the species or groups of species of interest.

The initial investment of time and money required to establish the validity of cost-effective marking techniques enables long-term savings through cheaper marking schemes. Many population level studies on animals are cost-prohibitive. For example, only two published mark-recapture studies are available for *S. lacertina* and more information on population monitoring is unavailable at this time. Prior to this study, only PIT tags were proven to work as a marking scheme and the cost of PIT-tagging a population of sirens would prevent many investigators from being able to conduct even a simple population estimate. Now that there are two cheap, quick, simple, and field-proven marking techniques for sirens, population monitoring is cheaper and more realistically achievable.

Acknowledgments.—I extend special thanks to C. Hickman, A. McKee, B. Morris, and C. Schalk for their assistance in the field. Their presence made even the hottest South Carolina summers all the more enjoyable. I thank my advisor, J. W. Gibbons, for his encouragement, field assistance, helpful review of the manuscript, and for providing me with an environment in which I was able to pursue various avenues of research as they presented themselves. I thank J. Earl for reviewing the manuscript and for providing several thoughtful comments. I thank my committee members,

G. Barrett and R. Sharitz, for providing constructive reviews, which greatly improved the quality of the manuscript. Finally, I thank R. Semlitsch and the anonymous reviewer for their insightful suggestions that greatly improved the final version of this manuscript. All procedures used in the study were approved by the University of Georgia Animal Care and Use Committee and by the South Carolina Department of Natural Resources Scientific Collection Permits. This research was supported by the American Museum of Natural History's Theodore Roosevelt Memorial Fund and the US Department of Energy through Financial Assistance Award Number DE-FC09-07SR22506 to the University of Georgia Research Foundation.

Marking Lizards by Heat Branding

BART VERVUST*

and

RAOUL VAN DAMME

Laboratory for Functional Morphology, Department of Biology
University of Antwerp, Universiteitsplein 1, B-2610 Antwerp, Belgium

Corresponding author; e-mail: bart.vervust@ua.ac.be

During a mark-recapture study on island populations of the lacertid lizard *Podarcis sicula* (Rafinesque-Schmaltz 1810), we needed to provide large numbers of lizards with individual, permanent marks. Toe clipping was not an option, because of the high incidence of natural toe loss in our study populations (see e.g., Schoener and Schoener 1980; Vervust et al., unpubl.). In addition, preliminary observations suggested that toe clipping may influence locomotor abilities and thereby reduce survival in this saxicolous species (Vervust et al., unpubl.). Techniques involving color banding or painting were discarded because they are insufficiently durable and/or might affect the lizards' visibility to predators. Passive integrated transponders (PIT tags) could not be used due to the small size of the lizards, especially the juveniles and subadults. Decimal coded wire tags (Northwest Marine Technology, Inc.) and visible implant elastomers (Northwest Marine Technology, Inc.) are not clearly visible in lizards and/or require sedation and later sometimes euthanization of the study animals.

Heat branding has been used to mark anurans (Taber et al. 1975; Thomas 1975; Daugherty 1976), salamanders (Taber et al. 1975; Bull et al. 1983; Woolley 1962), turtles (Woodbury and Hardy 1948; Clark 1971), lizards (Clark 1971) and snakes (Clark 1971; Lewke and Stroud 1974; Winne et al. 2006). Typically, marking-irons in the shape of numerals or alphabetic characters are combined to obtain different recognition codes. However, the total number of individuals that can be given a distinct code this way is limited by the number of shapes and is more cumbersome than necessary, especially in small animals. We decided to use a heat branding method and coding technique employed by Winne et al. (2006) to successfully mark snakes. The technique consists of marking specific combinations of ventral scales with disposable medical cautery units (Aaron Medical Change-A-Tip cautery high power units; Aaron Medical, St. Petersburg, Florida 33710, USA; www.aaronmed.com). We modified the coding system slightly for use in our study species. A first mark (R0) was burned on one of the first ventral scales on the right side of each individual, to act as a reference point. Second, third and fourth marks were then burned into other ventral scales. Each of these marks was given a name reflecting its position with regard to the reference point (Figs. 1, 2). For instance, a mark at the right side of the body, 5 scale rows below R0 would be called R5; a mark at the left side of the body, 3 scale rows below R0, would be L3. These marks were made on the outer ventral scale rows. These names could then be combined into an individual lizard's code (R5L3). The number of unique combinations that can be produced in this way is:

$$\sum_{k\,(0\to 3)} \frac{n!}{k!\,(n-k)!}$$

with k = the number of dots applied, exclusive of R0 and n = the number of ventralia available, exclusive of R0. In our study species, 24 rows of ventralia could be used for burning; the ventralia adjacent to the collaria and preanalia were often too small to allow proper marking. Hence, 48 lizards could be coded individually with one dot; 1,129 with two dot combinations, 17,344 with three dot combinations and 195,709 with four dot combinations (plus the reference dot). Since our study populations have estimated population sizes between 3000 and 9000 lizards (Vervust et al. 2007), we used a maximum of four dots per lizard (inclusive of R0).

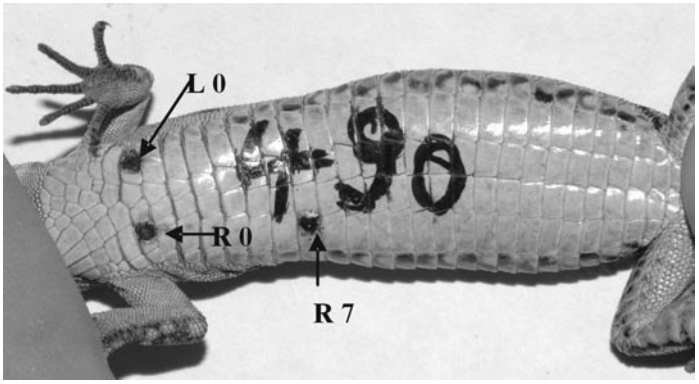

FIG. 1. Lizard from the islet Pod Kopište, with burn mark R7L0, after 48 h.

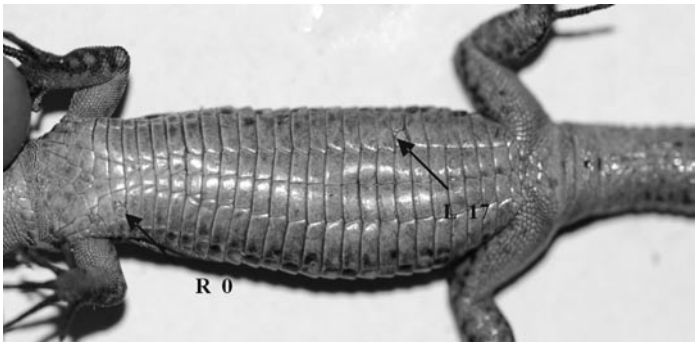

FIG. 2. Lizard from the islet Pod Mrčaru, with burn mark L17, after 465 days.

To date we have marked over 1000 lizards, including juveniles, with this technique. All lizards were kept and observed in captivity for 48 hours after marking. None showed any obvious negative effects and all lizards resumed their normal activities within minutes after the treatment. Not a single lizard died during this period. The markings remained clearly visible over a period of at least 485 days during which the lizards resided in their natural habitat (Fig. 2) and could be readily distinguished from natural scars.

Acknowledgments.—Research was carried out under research permit UP/I 612-07/04-33/267 issued by the Croatian Ministry of Culture. This study is part of larger projects supported by the FWO – Flanders (project nr. G.0111.06), the Institutional Animal Care and Use Committee at the University of Antwerp approved all procedures used in this project.

AMPHIBIAN DISEASES

This section offers a timely outlet for streamlined presentation of research exploring the geographic distribution, host range, and impact of emerging amphibian pathogens, especially the amphibian chytrid fungus *Batrachochytrium dendrobatidis* (*Bd*) and ranaviruses. *Bd* is an emerging pathogen linked to mass mortality and declines of amphibians worldwide, yet Bd has also been detected in amphibians without disease. Ranaviruses also cause mass mortality, but have not yet been linked to large-scale declines. We know relatively little about their global distribution, host range, or impacts on host populations. To improve our understanding of the scope of this issue, we encourage submission of studies that illuminate the geographic distribution, host ranges, and impact of these pathogens on amphibian populations, including research on individual species or groups of species, wild or captive animals, native or non-native species, live animals or museum specimens, environmental samples, and, provided there is sufficient sampling[1], reports of non-detections.

We ask authors to: 1) restrict the Introduction of their paper to a **maximum** of two paragraphs to highlight the context of their study; 2) briefly include both field and laboratory Methods; 3) present Results in a Table, although a map might also be useful, and limited text; and 4) have a short discussion of a **maximum** of three paragraphs to touch upon key findings. Please include the following information in submissions as appropriate: coordinates and description of sampling areas (or please note if locations are extremely sensitive to reveal, and provide general area instead); species name(s) and life history stages examined, as well as other species present; whether samples were collected randomly or just from dead or moribund animals; date of specimen collection; evidence of unusual mortality; numbers of positive and negative samples; disposition of voucher specimens; name of collaborative laboratory or researcher conducting histological sections or PCR analyses; and names of cooperative land owners or land management agencies. We encourage researchers to conduct post-mortem examinations when possible to identify the cause of death when reporting mortalities. We aim to expedite the review and publication process! Please e-mail submissions directly to Associate Editor, Dr. Dede Olson: dedeolson@fs.fed.us.

In the last few decades, rapid declines and extinctions of populations have been reported in more than 400 amphibian species all over the world. A pathogen that has received attention relative to these losses is the chytridiomycete *Batrachochytrium dendrobatidis* (*Bd*). Ron (2005) identified potentially suitable regions for *Bd* establishment in the New World. In South America, Ron predicted suitable regions included the Brazilian Atlantic forest, the temperate forest in Chile and western Argentina (south to 30ºS), northeastern Argentina, Uruguay, and Paraguay. Thus far in Argentina, *Bd* has been reported in four anuran species at three geographic locations: 1) Barrionuevo and Mangione (2006) found *Bd* in *Telmatobius pisanoi* and *T. atacamensis* (Anura: Leptodactylidae) in mountainous areas of Northern Argentina; 2) Arellano et al. (2006) and Herrera et al. (2005) reported *Bd* in adult specimens of *Leptodactylus ocellatus* (Anura: Leptodactilidae) in Buenos Aires province; and 3) in North Patagonia, Fox et al. (2006) found *Bd* in *Atelognathus patagonicus* (Anura: Leptodactilidae). We present *Bd* detections in central Argentina: a new occurrence in the Striped Thin-toed Frog (*Leptodactylus gracilis*) and another occurrence in the Spotted Thin-toed Frog (*Leptodactylus ocellatus*).

Dead specimens of the two leptodactilids were found during field surveys and were deposited in the collection of Centro de Zoologia Aplicada (Universidad Nacional de Córdoba, Argentina). A specimen of *Leptodactylus ocellatus* (CZA a-00011) was collected on May 2005 (31.3967ºS, 64.5936ºW) and a specimen of

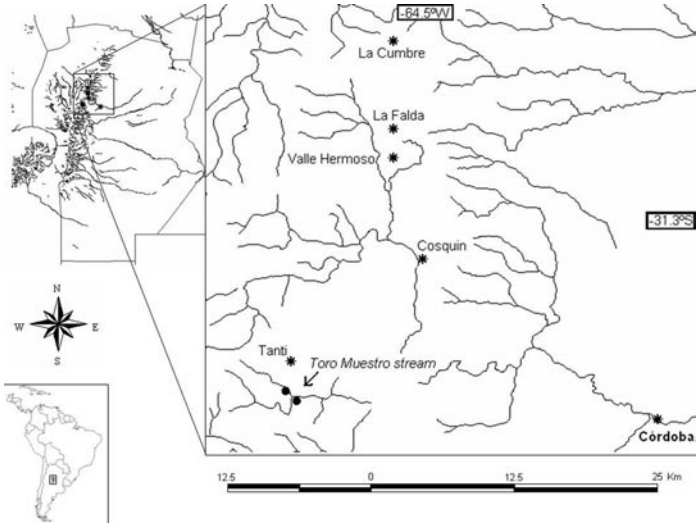

FIG. 1. Location of dead *Leptodactylus gracilis* and *L. ocellatus* specimens infected with the amphibian chytrid fungus, *Batrachochytrium dendrobatidis*, in central Argentina (black dots). Stars represent nearby localities.

Leptodactylus gracilis (CZA a-00010) was collected on March 2006 (31.3855ºS, 64.6057ºW), on the banks of the Toro Muerto stream, in the locality of Villa Flor Serrana, in a mountainous area of Córdoba province, Central Argentina, at 800 m elevation. The stream had a mean depth of 70 cm and flowed intermittently over granitic rock. The physiognomy of the surrounding vegetation was that of serrano secondary forest and thorny shrublands, typical of the Chacoan region (Cabrera 1976). Annual rainfall is 950 mm and is mainly concentrated in spring and summer. Mean annual temperature is 18.9°C, ranging from peak values in summer that may exceed 38°C to winter frosts (Capitanelli 1979).

The specimens were fixed in the field in 10% neutral formaldehyde solution and then were transferred to 70% ethanol. In the laboratory, abdominal and hind limb ventral skin patches (~5 x 10 mm) were excised from the anurans, stored in 70% ethanol and dehydrated to embed in paraffin. Then, tissues were sectioned at 5-μm thickness with a Reitcher microtome for histology, and stained with hematoxylin & eosin. With a stereomicroscope, we looked for spores and sporangia in the corneous epithelium of the tissue samples following Berger et al. (1999) and Pessier et al. (1999).

We identified *Bd* in the two specimens analyzed. Zoosporangia at different developmental stages, empty or containing rounded basophilic zoospores, were identified in the stratum corneum. With those results, we increase the geographic distribution of *Bd* in *Leptodactylus ocellatus*, and report the first record of infection in *L. gracilis*. These two species are widespread in a broad region of Argentina, supporting the need to conduct further studies of *Bd* to investigate the status of these populations and the risk to sympatric species. The first case of *Bd* in Argentina was detected in 2002 in a dead specimen (Herrera et al. 2005), and until now eleven specimens (include our two) belonging to five different species have been found infected (Arellano et al. 2006, Barrionuevo and Mangione 2006, Fox et al. 2006, Herrera et al. 2005). Our finding expands the known distribution of *Bd* to the wilderness area of the Chacoan phytogeographic region of Argentina, Chaco Serrano district (Cabrera 1976) (Fig. 1). Although Ron's (2005) prediction map of potentially suitable regions for *Bd* establishment

has constituted a helpful tool for orientating explorations for *Bd* infections detection, these prediction have been made on the bases of only 44 points over the New World, and none of these points was either from Argentina or neighboring countries, resulting in a low precision. Further information is needed about the prevalence and habitat requirements of *Bd* infecting anurans inhabiting Argentina for modeling an actualized and more precise *Bd* distribution map. An increase in the number of amphibian species monitored will help us to estimate the health of wild populations. The collection of environmental and biological data will provide us with valuable tools to predict new scenarios and implement adequate and specific conservation policies in order to manage disease outbreaks in Argentina.

Acknowledgments.—This work was partially founded by a grant (to GR) from Neotropical Grassland Conservancy and a fellowship (RG and JNL) from Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET). Protocols for maintenance and use of specimens followed the human and ethical rules in accordance with Animal Care guidelines. We thank Javier A. López for critically reading the manuscript.

Amphibians in the southern Appalachian Mountains of the United States comprise a diverse and globally significant biological resource (Dodd 2004). There are ample reasons to be concerned about the welfare of amphibian populations in the Southern Appalachians, given expected changes in environmental conditions with climate change (Bernardo and Spotila 2006; Corser 2001; Dodd 1997) and reports of population declines (Corser 2001; Highton 2005). Furthermore, the pathogenic fungus, *Batrachochytrium dendrobatidis* (hereafter called *Bd*), has been detected in many sites throughout the southeastern U.S. (e.g., Daszak et al. 2005; Rothermel et al. 2008). Although Rothermel et al. (2008) detected *Bd* infection in 10 species within the families Ranidae, Hylidae, and Salamandridae, none of the 143 amphibians collected in Great Smoky Mountains National Park in 1999–2001 were infected. Importantly, this sample included only two individuals in the family Plethodontidae. Other studies have reported *Bd* infections in wild-caught plethodontid salamanders of two terrestrial species (*Plethodon neomexicanus*, Cummer et al. 2005; *P. cinereus*, Lauer et al. 2007) and three stream-associated species (*Eurycea cirrigera*, Byrne et al. 2008; *E. bislineata* and *Desmognathus fuscus*, Grant et al. 2008). Researchers have also collected morbid terrestrial plethodontid species (*Oedipina* spp. and *Bolitoglossa* spp.) during mass mortality events in Mexico and Panama (Lips et al. 2003; Parra-Olea et al. 2005). Therefore, there is an urgent need for more information regarding *Bd* occurrence and susceptibility within the range of the many endemic species of salamanders in the Southern Appalachians.

Three methods have been used to detect the presence of *Bd* in amphibians: histological examination, conventional polymerase chain reaction (PCR), and quantitative (real-time) PCR (qPCR). The relative benefits of histological examination versus the more sensitive molecular methods have been described previously (Smith 2007). Since the publication of Boyle et al. (2004), qPCR has become widely adopted in studies seeking to detect or quantify the presence of *Bd* in amphibians. A recent study has supported the increased sensitivity of qPCR over conventional PCR in detecting *Bd* (Kriger et al. 2006), but there are few empirical tests

comparing the two methods (Kriger et al. 2006). The objectives of this study were: 1) to determine the presence of *Bd* in the Great Smoky Mountains of North Carolina and Tennessee; 2) to compare the incidence of *Bd* in groups of amphibians with different life history strategies (i.e., pond-breeding, stream-breeding, and fully terrestrial); and 3) to assess repeatability of *Bd* detection by verifying a subset of our conventional PCR results using qPCR.

Methods.—Field surveys for amphibians were conducted in Great Smoky Mountains National Park, located in western North Carolina and eastern Tennessee. We sampled pond-breeding amphibians from 10 sites in April and May 2007, and collected 377 larval and 60 post-metamorphic samples. We sampled stream-breeding and fully terrestrial salamanders from 25 sites in May–July 2006 and April–July 2007, and collected one larval and 221 post-metamorphic samples. Larvae were euthanized by immersion in a concentrated solution of MS-222, which does not destroy *Bd* (Webb et al. 2005). The sampling method for post-metamorphic amphibians entailed swabbing the ventral skin (and hind-toe webbing of anurans) 15–20 times, following the protocol of Livo (unpubl.; http://wildlife.state.co.us/NR/rdonlyres/710BBC95-2DCF-4CF9-8443-D4561DBC3B69/0/PCRsampling2004.pdf). Euthanized larvae and swab samples were preserved in 70% ethanol for subsequent genetic assays.

DNA isolation techniques for pond-breeding amphibians varied depending on whether the sample was a whole larva or a skin swab. For larvae, oral discs were excised and DNA was isolated using standard phenol-chloroform techniques. Briefly, oral discs were initially incubated in 100 μl of 1 mg/ml collagenase (Sigma-Aldrich Chemical Company, St. Louis, Missouri) in phosphate buffered saline (PBS) for 4 h at 37°C followed by an additional incubation using 100 μl of proteinase K for 16 h at 37°C. After incubation, the digested tissue samples were triturated to disrupt cellular matrixes and an equal volume of a 1:1 ratio of phenol:chloroform was added. The sample was vortexed thoroughly for 10 sec and allowed to set at room temperature for approximately 5 min. The sample was then centrifuged at 10,000 × g for 5 min and the top, aqueous layer was moved to a new tube. Approximately five volumes of 100% ethanol and 100 μl of 3 M sodium acetate were added to the sample for DNA precipitation. The samples were allowed to sit at -80°C for 5 min and then centrifuged at 10,000 × g for 10 min. The resulting DNA pellet was washed once in 80% ethanol and subsequently centrifuged at 10,000 × g for 5 min. The DNA pellet was air dried and resuspended in 20 μl of molecular grade water.

Larvae collected in the field were either kept separate for individual analysis or pooled. The oral discs of separated individuals (N = 90) were kept isolated and processed separately throughout. However, some pooled samples (N = 293 individuals) of larvae were large (as many as 73 tadpoles per jar) and had to be divided into subsamples of three to seven oral discs per tube (N = 66 reactions). Pooled samples of pond-breeding amphibian larvae consisted of only a single species. In addition to testing the oral discs, we also retained and tested the ethanol from each pooled sample of larvae (N = 8). The ethanol was passed through a 0.22 μm filter to collect possible free-floating *Bd* zoospores. The cellular debris was reverse-osmosed to collect the debris in a new tube. The sample was then boiled in a hot water bath and the resulting cell lysate was frozen until further DNA analysis. To isolate DNA from skin swabs (N = 199), we pressed the swab against the sides of its 2-ml vial to remove most of the retained ethanol (and any *Bd*) from the cotton. The tubes containing ethanol were then centrifuged to create pellets of swab-debris and possible zoospores. The swab-debris pellet was re-suspended in water and boiled. The resulting cell lysate was frozen until used directly for PCR analysis; cell lysates of *Bd* were not found inhibitory to PCR reactions (C. S. Brooks, unpubl. data). All pond-breeding amphibian samples were analyzed using conventional PCR following Annis et al. (2004). As controls, the above procedures were repeated using *Bd*-free swabs and frog tissues intentionally inoculated with serially diluted zoospores to determine minimum detection limits. These controls indicated that as few as 10 zoospores could be detected using the described procedures (C. S. Brooks, unpubl. data).

DNA was extracted from swabs collected from stream-breeding and fully terrestrial salamanders following the methodology of Hyatt et al. (2007). Swab samples were tested for the presence of *Bd* DNA using qPCR Taqman assays and species-specific primers developed by Boyle et al. (2004). With our limited funding, we chose to use this more expensive (and presumably more sensitive) analytical method for only the samples of plethodontids. Plethodontids are of greater concern from a conservation standpoint and use of qPCR ensured a high degree of confidence in negative results. An internal control (VIC_{TM} dye, Applied Biosystems) was added to every sample well of the assay, and was used to determine the presence of PCR inhibitors, which may result in false negatives (Hyatt et al. 2007). Additionally, a sample known to contain *Bd* was run concurrently as a positive control. To avoid the high costs associated with qPCR, samples from identical locations (but not necessarily the same species) were pooled, with up to three samples per reaction well (Hyatt et al. 2007). To further avoid high costs, all assays were performed in singlicate (following Kriger et al. 2006) rather than the widespread method of performing assays in triplicate (following Boyle et al. 2004). Actual detection probability is not expected to decline significantly with these cost-cutting measures (Kriger et al. 2006; Hyatt et al. 2007).

To assess repeatability of *Bd* detection, 15 samples from the pond-breeding group that tested positive and 20 that tested negative using conventional PCR were rerun using qPCR. Five positive controls of differing concentrations (undiluted and dilution factors of 1/20, 1/400, 1/8000 and 1/160000) were also run using qPCR. Samples were run in triplicate at 1/10 and 1/100 dilution factors (for a total of six replicates per sample). Samples were scored as negative if all six of the replicates tested negative, positive if three to six replicates tested positive and equivocal if one or two of the replicates tested positive. These tests were conducted blindly, such that the number and identity of samples that tested positive using conventional PCR was not known during the qPCR analysis.

Results.—Using conventional PCR, we detected *Bd* in samples from four of the 10 localities where pond-breeding amphibians were collected. All positive samples using this method were larval anurans, with five to 116 infected Wood Frog (*Lithobates sylvaticus*) larvae, one infected toad (*Anaxyrus* sp.) larva, and one to seven chorus frog (*Pseudacris* sp.) larvae being detected (Table 1). The above ranges of infected *Lithobates* and *Pseudacris* larvae are large because it is impossible to determine how many individuals within a pooled set of samples were infected. At sites where *Bd* was detected, prevalence was apparently very low. We can

TABLE 1. Post-metamorphic (P) and larval (L) amphibians tested for *Batrachochytrium dendrobatidis* (*Bd*) infection in Great Smoky Mountains National Park, North Carolina and Tennessee, USA, in 2006–2007.

* Numbers in parentheses indicate number of samples tested after pooling.

infer prevalence from samples in which large numbers of larvae were collected from a given site on the same date, and individual larvae were preserved and analyzed separately. At Finley Cane Sinkholes (35.61027°N, 83.74388°W), only 1.6% of toad larvae were infected. At Stupka's Sinkhole (35.58972°N, 83.84777°W), 3.7% of Wood Frog larvae were infected. Likewise, the one positive subsample of Wood Frog larvae from Finley Cane Sinkholes contained three larvae (out of a total of 72), which suggests prevalence was ≤ 4%. These sites are in, or within 10 km of, the heavily visited Cades Cove area in the western section of the park.

According to the qPCR assays, every stream-dwelling and terrestrial salamander swab sample was negative for the presence of *Bd* (Table 1). By determining the presence of *Bd* in the positive control, we confirmed that the reactions worked. However, the standard dilution of 1/10 (Hyatt et al. 2007) of the swab extract yielded a mere 20% success rate in internal control reactions, indicating PCR inhibition was a significant problem. To overcome the presence of PCR inhibitors, all samples were rerun with a 1/100 dilution. The success rate of internal control reactions was 100% following the increased dilution factor.

Results of samples analyzed using both conventional PCR and qPCR were largely discordant. Of the 35 samples that were run using conventional PCR and subsequently rerun using qPCR, 14 were discordant with the original result, 13 were concordant and 8 were equivocal. In total, seven additional samples unequivocally tested positive using qPCR: two *Lithobates sylvaticus* larvae from The Sinks (35.66944°N, 83.66138°W; ca. 14 km from Cades Cove), one *L. sylvaticus* larva from Finley Cane Sinkhole, one *L. sylvaticus* larva from Tremont Road (35.65222°N, 83.69722°W; ca. 10 km from Cades Cove), and three post-metamorphic *Notophthalmus viridescens* from Stupka's Sinkhole (Table 1). Importantly, *Bd* infection would not have been detected in *N. viridescens* had the samples not been retested using qPCR. Conversely, 7 samples that tested positive using conventional PCR tested negative using qPCR. It is also important to note that positive controls had predictable results. The undiluted positive control and the control diluted to 1/20 tested positive, the control diluted to 1/400 was equivocal (consistent with a very low concentration) and the controls diluted to 1/8000 and 1/160000 tested negative (consistent with concentrations too low to detect).

Discussion.—Our sampling revealed the presence of *Bd* in a limited number of sites and species within Great Smoky Moun-

tains National Park. The detection of *Bd* in the Park is one of a growing list of occurrences in the southeastern U.S. For example, recent surveys have also found *Bd*-infected amphibians at Congaree National Park in South Carolina, Chattahoochee River National Recreation Area in Georgia, and sites in the Blue Ridge Mountains of North Carolina and Georgia (Rothermel et al. 2008).

Another goal of this study was to provide preliminary information regarding *Bd* prevalence and which species are infected. We detected *Bd* in the larval stages of pond-breeding anurans in the genera *Anaxyrus*, *Lithobates*, and *Pseudacris*, as well as in post-metamorphic pond-breeding salamanders (*Notophthalmus*). Overall prevalence in the park appears to be low (1–4%), but exact measures of prevalence are not possible because we had low sample sizes for many sites and individual larvae were often pooled by species and site. We could not assess the influence of elevation on *Bd* occurrence because elevation and taxonomic associations were confounded; that is, samples (including positives) of pond-breeding species tended to be from lower-elevation sites and samples (all negative) of stream-dwelling and terrestrial salamanders tended to be from higher-elevation sites. Woodland salamanders that are direct-developing may have a low likelihood of infection simply because they do not inhabit streams and other aquatic habitats where *Bd* occurs. However, at least one species (*Plethodon metcalfi*) has been shown to be susceptible to chytridiomycosis following experimental exposure to *Bd* (V. M. Vazquez and B. B. Rothermel, unpubl. data). Resistance to *Bd* in some species derives from antimicrobial peptides produced by skin glands (Rollins-Smith et al. 2005) or cutaneous bacteria that inhibit growth of fungi, in some cases (Harris et al. 2006; Lauer et al. 2007). Different species and populations possess various combinations of these inhibitory factors, resulting in variation in resistance to chytridiomycosis.

The simplest explanation for the discordance in conventional PCR versus qPCR results is that *Bd* occurs with such low prevalence in the Great Smoky Mountains that repeated tests on the same sample yield only occasional positives. The implications of this finding are: 1) that large sample sizes may be necessary to detect the presence of *Bd* where present; and 2) current estimates of prevalence may be underestimates. Our comparative tests also suggest that conventional PCR detection rates may not be significantly lower than those of qPCR, although additional studies with larger sample sizes are needed.

Acknowledgments.—We thank L. Robertson, J. Miller, A.F. Scott, J. Love, M. Vance, K. Hamed, V. Chatfield, and the Spring 2007 Herpetology class from APSU for assisting in field work. We also thank D. Henley, A. Zellmer, and C. Richards for assistance in the lab, and J. Longcore for providing *Bd* cultures. Funding for this study was provided by an Appalachian Highlands Network Research Grant through the National Park Service, as well as The Center of Excellence for Field Biology and an APSU Faculty Research Award to C. Taylor and B. Rothermel. This research was performed in accordance with permits from the National Park Service (GRSM-2007-SCI-0012) and the states of North Carolina and Tennessee, and an approved Animal Care & Use Protocol (07-006) from Austin Peay State University.

Amphibian Chytrid (*Batrachochytrium dendrobatidis*) in Post-Metamorphic *Rana boylii* in Inner Coast Ranges of Central California

JASON LOWE
U.S. Bureau of Land Management, 20 Hamilton Court
Hollister, California 95023, USA
e-mail: jason_lowe@blm.gov

In California, USA, the amphibian chytrid fungus, *Batrachochytrium dendrobatidis* (*Bd*), has been reported to infect many species of native ranids (Nieto et al. 2007; Padgett-Flohr 2007) with particular attention being focused on dramatic *Bd*-related declines of the Sierra Nevada Yellow-legged Frog (*Rana sierrae*) in the Sierra Nevada mountains (Davidson et al. 2007; Fellers et al. 2001; Rachowicz et al. 2006). The Foothill Yellow-legged Frog (*R. boylii*) is a close relative of *R. sierrae* that occurs in streams over much of California, but at lower elevations (<1940 m) than *R. sierrae* (Fellers 2005). In 2006, *Bd* was found in *R. boylii*, Pacific Treefrogs (*Pseudacris sierra* sensu Recuero et al. 2006a, b), and Western Toads (*Anaxyrus boreas*) at Pinnacles National Monument, managed by the US Department of Interior - National Park Service, and in nearby streams on lands managed by the US Department of Interior - Bureau of Land Management (BLM) in San Benito and Fresno counties (P. Johnson, pers. comm.). The BLM in California recognizes *R. boylii* as a sensitive species, and it is a California Species of Concern (http://www.dfg.ca.gov/wildlife/species/ssc/amphibians.html). I surveyed *R. boylii* from nine streams in this region and tested them for *Bd* to better understand the geographic distribution of the pathogen. Incidental captures of *P. sierra* also were tested. In addition, I conducted a preliminary investigation of potential differences in habitat associations of infected and non-infected *R. boylii*.

Methods.—Between 5 July and 14 September 2006, post-metamorphic *R. boylii* and *P. sierra* were opportunistically caught during abundance counts conducted using visual encounter surveys (Fellers and Freel 1995) along streams in the Inner Coast Ranges of central California (Fig. 1). During abundance counts, frogs were recorded as adults or subadults subjectively based on size. Skin swabs were collected from each captured frog and screened for *Bd* presence using PCR amplification (Pisces Molecular LLC, Boulder, Colorado, USA). Sterilized equipment and disposable gloves were used for each frog handled. Snout–vent length (SVL), weight, and sex were recorded for each frog. For each capture location, microhabitat variables were recorded including water temperature, water depth, stream width, water velocity, stream habitat unit type (riffle, run, pool, step-pool), dominant substrate size (modified from Platts et al. 1983; sand [<2 mm diam], gravel [2–63 mm], cobble [64–256 mm], boulder [>256 mm]), dominant riparian vegetation, and location by Universal Transverse Mercator. Two-sample t-tests were used to compare continuous variables (SVL, weight, SVL-to-weight ratio, water temperature, water depth, and stream width) between *Bd*-negative and *Bd*-positive samples using NCSS 2000 statistical software. To assess frog condition between those animals with and without *Bd*, SVL-to-weight ratios were compared. Categorical variables (sex, stream habitat unit, substrate, and vegetation) did not yield adequate within-group samples sizes for statistical analysis, hence summaries for these variables are given.

Results.—Forty-nine *R. boylii* were tested for *Bd* from nine streams, and seven *P. sierra* were tested from three streams and a BLM vehicle wash facility. Nine of 49 (18%) *R. boylii* and one of seven (14%) *P. sierra* tested positive for *Bd*. Five of nine (56%) streams supporting *R. boylii* had at least one frog testing positive for *Bd* (Fig. 1, Table 1). Different streams were tested during different months of the year. All streams tested in July had *Bd*-positive frogs, as did half the streams tested in August, but no streams tested in September had *Bd*-positive frogs. Frogs at one stream, White Creek, tested positive for *Bd* during pilot sampling in May but tested negative in September. *Bd*-positive frogs occurred in streams with low *R. boylii* densities (e.g., 41 post-metamorphic frogs/km) to high *R. boylii* densities (e.g., 527 post-metamorphic frogs/km, Table 1). The single *Bd*-positive *P. sierra* was captured at Sawmill Creek where one *R. boylii* was also *Bd*-positive. The remaining *P. sierra*, including two captured from the vehicle wash facility, tested negative for *Bd*.

Rana boylii of all size classes (15–75 mm SVL) were tested, but only smaller frogs (<41 mm SVL) tested positive for *Bd* (Fig. 2). Although there was no significant difference in SVL between *Bd*-positive and *Bd*-negative groups ($p = 0.1260$, $t = 1.558$), *Bd*-positive frogs weighed less (mean *Bd*+ = 3.4 ± 0.6 SE, N = 8;

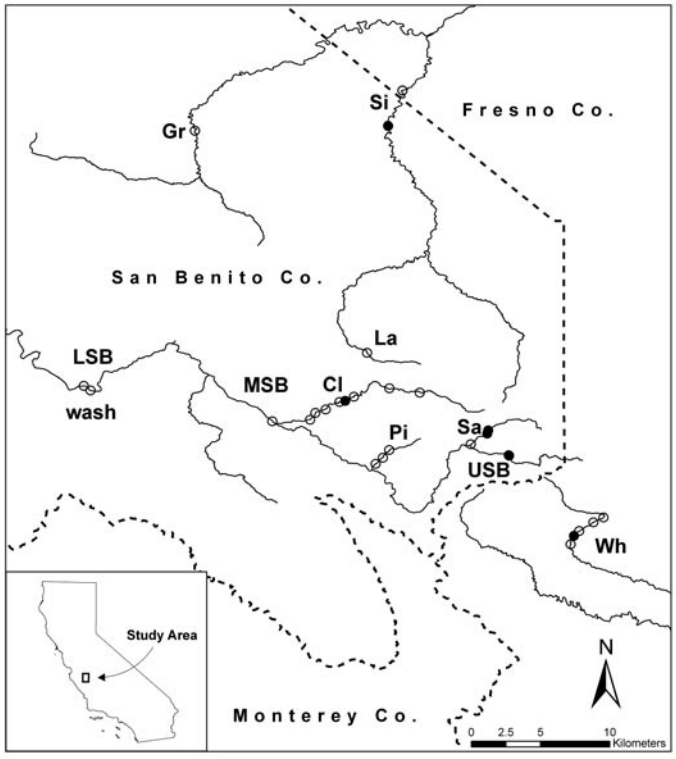

FIG. 1. Locations of positive (black circles) and negative (open circles) test results for *Batrachochytrium dendrobatidis* in *Rana boylii* and *Pseudacris sierra* in Griswold Creek (Gr), Silver Creek (Si), Larious Creek (La), lower San Benito River (LSB), vehicle wash facility (wash), middle San Benito River (MSB), Clear Creek (Cl), Picacho Creek (Pi), Sawmill Creek (Sa), upper San Benito River (USB), and White Creek (Wh), California, USA.

TABLE 1. Streams surveyed for *Rana boylii* density (frogs/km) and results of *Batrachochytrium dendrobatidis* (*Bd*) tests in 2006 in southern San Benito and western Fresno counties, California, USA.

Stream Name	Adult Density	Sub-adult Density	No. Frogs Tested for *Bd*	No. *Bd*-Positive Frogs	Date of Samples
White Creek	92	435	11	0[a]	8 Sept
Clear Creek	54	205	14	1	27 July
San Benito River (upper)	53	54	6	4	12 July
Picacho Creek	25	153	5	0	1,5 Sept
Larious Creek	14	0	2	0	9 Aug
Sawmill Creek	12	9	2	1[b]	5,7 July
Silver Creek	8	33	6	3	17 Aug
San Benito River (lower)	2	3	2	0	7 Sept
San Benito River (middle)	0	9	1	0	7 Sept

[a] Although negative for *Bd* in September, a pooled sample of 10 *Rana boylii* from White Creek tested positive for *Bd* during pilot sampling on 9 May 2006.
[b] One *Pseudacris sierra* from Sawmill Creek was *Bd*-positive.

mean *Bd*- = 8.8 ± 1.2 SE, N = 39; p = 0.0282, t = 1.958). Smaller frogs (< 41 mm SVL) testing positive for *Bd* had higher SVL-to-weight ratios than frogs of the same size class testing negative for *Bd* (mean *Bd*+ = 8.0 ± 0.5 SE, N = 5; mean *Bd*- = 6.9 ± 1.0 SE, N = 16; p = 0.0174, t = -2.274). Frogs > 41 mm SVL were not included in this analysis. Because of their small sizes, none of the nine *R. boylii* testing positive for *Bd* could be sexed. Frogs that tested positive were not symptomatic for chytridiomycosis, and no frogs seen during abundance counts appeared abnormal in any way. However, one sub-adult *R. boylii* was found dead at the bottom of White Creek being consumed by a stink bug (Pentatomidae).

Bd-positive frogs were found in streams with various types of riparian vegetation (e.g., Brewer's Willow [*Salix breweri*], Salt Cedar [*Tamarix ramosissima*], and California Sagebrush [*Artemisia californica*]) and in various aquatic habitat conditions, but primarily in pools with fine substrates and cooler than average water. Eight of the nine (89%) *Bd*-positive *R. boylii* and the *Bd*-positive *P. sierra* were caught in pools, even though pools made up only 43% of the frog capture locations. The other *Bd*-positive *R. boylii* was captured in a high-velocity riffle with a gravely substrate from Clear Creek. All the *Bd*-positive pools had sandy substrates except those on the upper San Benito River, which had cobble-dominated substrate. Water temperatures were lower at *Bd*-positive sites (mean *Bd*+ = 20.0 ± 1.6 SE, N = 9; mean *Bd*- = 23.7 ± 0.5 SE, N = 40; p = 0.0102, t = 2.678). When riffles and runs are taken out of the analysis to compare water temperatures of pools only, the pattern of cooler temperatures at sites with *Bd*-positive animals remains significant (mean *Bd*+ = 20.2 ± 1.8 SE, N = 8; mean *Bd*- = 23.3 ± 0.8 SE, N = 13; p = 0.0475, t = 1.757). Stream width (range 0.5–4.5 m) and water depth (4–68 cm) did not differ between sites with *Bd*-positive and *Bd*-negative frogs (p = 0.7421, t = 0.3310; p = 0.4668, t = 0.7337, respectively).

Discussion.—I detected *Bd* in 18% of the *R. boylii* sampled, and in 5 of 9 streams in southern San Benito and western Fresno counties, California. The small sample size from some streams might explain lack of detection, given the relatively low prevalence rate across all sampled frogs. Interestingly, none of the streams sampled in September resulted in *Bd*-positive results even though one of these was known to have *Bd*-positive frogs in May. Other studies have shown that higher prevalence and mortality rates of *Bd* are detected in winter and early spring than in late summer and early fall (Berger et al. 2004; Kriger and Hero 2006, 2007). Streams in the present study were sampled during various months of the summer, and a seasonal effect may have confounded analyses. If a seasonal effect resulted in false negatives for frogs tested in September, then the pattern of *Bd* distribution in the study area and the overall prevalence rate described here could be underestimated.

I found that only *R. boylii* less than 41 mm SVL and weighing less than 4.0 g tested positive for *Bd*. Frogs of this size are young-of-the-year or sub-adults in their second post-metamorphic year (Stebbins 1962; Storer 1925; Zweifel 1955). These younger age classes had reduced body condition (as estimated by SVL-to-weight ratio) if they tested positive for *Bd*. No adults in this population tested positive for *Bd*, which might indicate a difference in *Bd* susceptibility between these life history stages. Desiccation and temperatures over 30ºC are known to be lethal to Bd (Daszak et al. 2000; Drew 2006; Johnson et al. 2003), and *R. boylii*, especially adults (pers. obs.), are known to bask on open

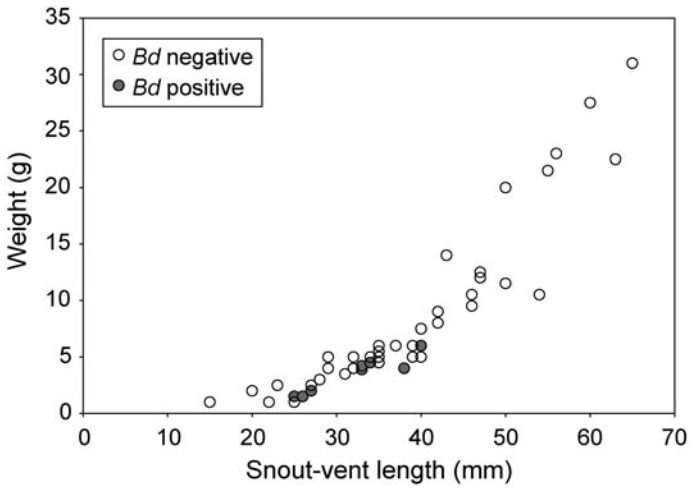

FIG. 2. Sizes of 48 *Rana boylii* tested for *Batrachochytrium dendrobatidis* (*Bd*) in California, USA. *Bd*-positive individuals (N = 8) are shown in black. One *Bd*-positive frog (33 mm SVL) was not weighed.

sunny stream banks with less than 20% canopy cover (Fuller and Lind 1992; Stebbins 1962). This behavior might prevent *Bd* from infecting *R. boylii* adults or help them to shed the fungus if infected, especially in the foothills of California where summer air temperatures commonly exceed 35ºC. Although, mortality of *Bd*-infected adults cannot be ruled out, no evidence for adult chytridiomycosis or mortality was seen in this study.

Pool habitats and cooler water temperatures were the only habitat variables that were significantly associated with the presence of *Bd*. Pools provide rearing habitat for *R. boylii* larvae, and in one study, *R. sierrae* larvae have been shown to transmit *Bd* to post-metamorphic frogs (Rachowicz and Vredenberg 2004). The preponderance of *Bd*-positive frogs sampled from pools where larvae tend to congregate appears to support Rachowicz's suggestion that larvae and thus their habitats might serve as reservoirs for the fungus. It is uncertain whether the finding that *Bd*-positive frogs were sampled from areas with cooler water temperatures than *Bd*-negative frogs has any biological significance because the difference in water temperatures between these groups was small (20ºC versus 24ºC respectively) and within *Bd*'s optimal growth range of 17–25ºC (Daszak et al. 2000; Piotrowski et al. 2004).

Populations of *R. boylii* appear to be stable in streams involved in this study (BLM, unpubl. data, 2005–2007). The fact that large populations of *R. boylii* are present in streams with *Bd*-infected animals without showing declines or symptoms of chytridiomycosis is encouraging. However, if *Bd* is causing reduced body condition in younger age classes, population sizes might eventually be affected. This study was conducted over only one year, with small sample sizes, and might have been confounded by seasonal effects. I suggest future sampling be temporally stratified across seasons and years, with greater sample sizes of frogs tested. Furthermore, population monitoring to determine the lethality of *Bd* on various life history stages, prevalence rates, and population-level effects in various streams over time is warranted given the sensitive status of the species and the effects the disease has had on its close relative *R. sierrae*.

How Relevant is Opportunistic *Bd* Sampling: Are We Ready for the Big Picture?

BRITT SPURRE PEDERSEN
and
FINN SPURRE PEDERSEN
Mosevaenget 8, DK-4900 Nakskov, Denmark

Understanding the distribution of chytridiomycosis, both at global and local scales, is important to controlling its impacts on host species (e.g., biocontrol or eradication) and to managing host amphibian populations (e.g., reintroduction and habitat management). In response to this, efforts to map observations of *Batrachochytrium dendrobatidis* (*Bd*) are underway to better understand its distribution and impact on amphibian populations (e.g., www.spatialepidemiology.net\Bd).

While there are many legitimate reasons to sample opportunistically for this pathogen, we question the validity of continuing this sort of exercise without a more cohesive and directed effort to apply the information to management of *Bd*. We use a recent example (Scalera et al. 2008) and some additional data from Denmark to discuss this question.

Scalera et al. (2008) published data from frogs (*Rana esculenta* [now *Pelophylax esculentus*], and *R. temporaria*) at sites in Denmark on the islands of Zealand (1 of 7 positive for *Bd*) and Fyn (1 of 4 positive for *Bd*). Two sites on the Jutland mainland of Denmark were negative according to Scalera et al. (2008) and a single positive record is known from the island of Bornholm, the most eastern portion of Denmark (www.spatialepidemiology.net). To these published data we add information from the island of Lolland where we tested 10 adult *R. esculenta* (three female and seven male) for *Bd* (sensu Berger et al. 2005). These animals were from a single pond in the backyard of a private residence on the outskirts of Nakskov (54.85°N, 11.01°E). Swabs were analyzed using PCR (Annis et al. 2004) at Pisces Molecular (Boulder, Colorado, USA) and *Bd* was detected on 0 of 10 animals.

Our data increase the range of sampling in Denmark to include four of six of the major islands (Zealand, Lolland, Fyn, and Bornholm). To date, there are no samples from Mon, Falster and the smaller islands of Als, Aero, and Langeland. The information reported here and by Scalera et al. (2008) is interesting because it is from a region lacking in data and provides the most northerly published records of this fungus in Europe (www.spatialepidemiology.net\Bd). However, there are serious constraints to these data.

Sampling in both reports (Scalera et al. [2008] and the present one) was ad hoc, sample sizes were low, and most sites yielded negative results. Scalera et al. (2008) tested a maximum of four adults or three juveniles per site. We tested 10 adults at one site. Skerratt et al. (2008) provides a good example of necessary sample sizes that contrast with those reported here and in many other reports (e.g., Zellmer et al. 2008, N = six per site; Adams et al. 2007, N = 2–17 per site). For example, if we assume perfect specificity of the PCR, and use an apparent prevalence ≥ 5%, 59 individuals must be sampled to be 95% certain of detecting *Bd* on at least one animal (Skerratt et al. 2008). This suggests that the sample sizes from locations in Denmark need to be at least six times greater to be confident in the negative reports. Alternatively, small sample sizes can be informative at high prevalence rates, but given reported sample sizes, prevalence rates would have to be 30% in our work, and at least 75% in the work by Scalera et al. (2008), to be 95% certain of detecting *Bd* on at least one animal. In populations that are not declining, we would expect the prevalence of *Bd*, if it is present, to be low in contrast to high values reported in amphibian communities where *Bd* is causing extinctions (e.g., 98% prevalence, Lips et al. 2006).

Clearly, neither the data presented by Scalera et al. (2008) nor our data are adequate to determine if the amphibian chytrid is absent from portions of Denmark. Additionally, these data cannot speak to the prevalence of the disease where it was detected (Skerratt et al. 2008). These reports beg the question, "What do we really know about the presence of the amphibian chytrid fungus in Denmark?" We submit that these reports tell us very little. Specifically, the information does not provide a clear direction or purpose for further testing because we are uncertain about the applicability (area of inference) and the degree of confidence we should attribute to the results. This hampers our ability to discuss the relationship of these data to other *Bd* occurrences in northern Europe, an exercise that has the potential to be relevant to at-risk amphibians in northern Europe and amphibian declines in general.

As observations of *Bd* are published and added to existing databases, it is tempting to try to interpret the "patterns" that begin to emerge which can be at best heuristic and at worst seriously misleading. Because of the well-known impact of chytridiomycosis on amphibians, the relative ease of sampling for the disease and the awareness level in the herpetological community, sampling and testing for *Bd* is often undertaken. Such opportunistic sampling is generally motivated by goals other than determining the distribution of *Bd* in a particular region or country. It can be quite useful to know whether *Bd* is present at a particular study site. For example, testing surrogate local amphibians or testing the environment for *Bd* (Kirshstein et al. 2007, Walker et al. 2007) is likely to be a critical element in translocation programs involving susceptible species (Walker et al. 2008). There is some utility to reporting the ad hoc testing of amphibians and locations for *Bd*, even when results are negative, especially when reports: 1) come from areas with no information at all; or 2) can be combined to present a picture of an area where a more concerted effort is unfunded or logistically difficult. Perhaps the real utility of these data lies in the archiving and mapping realm effectively implemented at www.spatialepidemiology.net\Bd.

On the other hand, we can argue that by continuing to report on isolated instances of positive and negative results, we are losing focus on the bigger issue of a single pathogen with global impacts. Two main issues surface, first, sample sizes are often low and ad hoc reports generally lack details on assay specificity, and laboratory and collection conditions. Second, much of the opportunistic sampling occurs in portions of the world where amphibians are already declining, the *Bd* "hot spots" of South and Central America and Australia. Are other locales being neglected because there is no globally coordinated sampling plan? Northern Europe is far

removed from typical *Bd* "hot spots" where species are highly impacted by this fungus and it is possible that declines in amphibian populations, caused or exacerbated by *Bd*, could go unnoticed in countries such as Denmark. While data exist on *Bd* for almost every biome in the world, including the temperate zone (e.g., Bosch et al. 2001 [Spain], Muths et al. 2003 [U.S.], Ouellet et al. 2005 [Canada]), there are information gaps where no scientists or funded projects exist, especially in regions where the perceived threat from *Bd* is low (i.e. northern regions).

There is no global amphibian authority to provide direction for coordinated sampling or to enforce collaboration, however, the Amphibian Conservation Action Plan (Gascon et al. 2007) calls specifically for more coordinated research into this disease. Perhaps an effort by the amphibian research community to follow a standard sampling plan is a first step. For example, Skerratt et al. (2008) have laid out a *Bd* sampling protocol using systematic sampling and taking into consideration time of year, accessibility, likelihood of infection, life stage, potential for pooling samples, and the specificity of the assay. This protocol was designed for the large land mass of Australia, but is applicable to any regional or country-wide effort in the rest of the world and offers the potential for a great deal of consistency in efforts to map and understand the distribution of *Bd*.

There is a significant challenge to moving ahead toward an understanding of the spatial epidemiology of chytridiomycosis and continued ad hoc additions to the existing databases are unlikely to yield answers. A systematic approach to building and testing hypotheses and bridging data gaps is necessary. Fortunately the substantial body of knowledge about the geographical distribution of this pathogen gained from coordinated regional efforts, as well as opportunistic sampling, provides the data necessary to develop such an approach.

Acknowledgments.—This project was approved by The Forestry and Natural Resources Board, Denmark. We thank M. Adams, D. Olson, and anonymous reviewers for comments that improved the manuscript. Mention of a specific manufacturer is not an endorsement but for information purposes only.

Blanchard's Cricket Frog (*Acris crepitans blanchardi*) is a small anuran with a broad distribution in North America (Conant and Collins 1998), and recently has been suggested for elevation to full species (Gamble et al. 2008). Cricket Frog populations are in decline throughout much of the northern portion of their range, although causes for these declines are unclear (Lannoo 2005). However, *A. c. blanchardi* is often the most abundant and conspicuous member of anuran breeding assemblages throughout much of the year in eastern and central Texas. Central Texas supports a particularly robust population, with Cricket Frogs found in virtually any natural or artificial aquatic environment, including ephemeral streams and pools, spring outflows, stock tanks, roadside ditches, and along riverbanks. At the eastern edge of the Edward's Plateau, *A. c. blanchardi* is sympatric with a number of endangered, threatened, or endemic amphibians including the Houston Toad (*Bufo* [*Anaxyrus*] *houstonensis*) (Hillis et al. 1984) and several species of plethodontid salamanders (*Eurycea nana*, *E. neotenes*, *E. pterophila*, *E. rathbuni*, *E. sosorum*) (Chippindale et al. 2000) each with increasing conservation concern in this rapidly developing region.

Amphibian populations are declining at an alarming rate world-

wide (Houlahan et al. 2000; Stuart et al. 2004), and infection by *Batrachochytrium dendrobatidis* (*Bd*) is frequently implicated as a factor in documented cases of population decline (Daszak et al. 1999; Daszak et al. 2000). *Bd* seems to be widespread in North America (Ouellet et al. 2005), and has been detected in both captive and wild populations of *A. c. blanchardi* in several states in the midwestern United States (Steiner and Lehtinen 2008; Zippel and Tabaka 2008). Detection of *Bd* on individuals of *A. c. blanchardi* was not restricted to regions with declining populations, and also not accompanied by any mortality or signs of chytridiomycosis (Steiner and Lehtinen 2008). Previous studies indicate that *Bd* can have variable effects on amphibian populations, with potential impacts ranging from no mortality to mass die-offs without recovery as the most extreme effects (Daszak et al. 1999; Daszak et al. 2003). The susceptibility of amphibians to *Bd*, however, can vary across species, developmental stage, and temperature regimes (Berger et al. 2004; Daszak et al. 2004; Davidson et al. 2003; Lamirande and Nichols 2002). In addition, seasonal variation in prevalence and severity of infection by *Bd* within individual populations has been noted (Bradley et al. 2002; Woodhams and Alford 2005; Kriger and Hero 2007), suggesting effects of environmental conditions on the severity of infection.

The purpose of this study was to determine the rate of infection by *Bd* within a population of *A. c. blanchardi* at the headwaters of Barton Creek, located ca. 11 km W of Dripping Springs and 30 km W of Austin, Texas (30.2248611°N, 98.1687306°W), adjacent to habitat for several endemic and endangered salamanders (Chippindale et al. 2000; Sweet 1982). We conducted a second sampling and subsequent analysis of frogs captured later in the season at the same site during times with higher mean temperature and lower water availability and we examined seasonality of the infection across a relatively narrow time scale.

Frog sampling was conducted on 18 May and on 18 July 2008. Weather data collected for the 30 days preceding sampling differed significantly between sampling events, with a mean temperature of 21.6 ± 0.6ºC and total precipitation of 57.1 mm for the May sampling date, and a mean temperature of 27.6 ± 0.4ºC and total precipitation of 18.8 mm for the July sampling date (Fig. 2). In May, the creek was flowing and several pools of considerable size (10 m^2–50 m^2) provided habitat for large numbers of cricket frogs. In July, sampling sites along the creek were virtually dry, with only a few predominantly mud-filled patches of habitat remaining. Frogs were much less abundant than in May, and two weeks after the July sampling frogs were completely absent from the sample site.

For the May sampling, which was part of a larger population genetics study of *Acris*, 30 frogs were captured by hand and uniquely marked using a series of toe clips (Hero 1989). These toes as well as toes from 27 individuals obtained in July were retained and stored in 95% EtOH until used for DNA extraction. DNA extracts were tested for the presence of *Bd* using a nested PCR approach that has shown high sensitivity of detection and is outlined in detail in Gaertner et al. (*in press*). This procedure uses primers ITS1f (5'-CTT GGT CAT TTA GAGC GAA GTA-3') and ITS4 (5'-TCC TCC GCT TAT TGA TAT GC-3') to amplify the 5.8S rRNA gene and the flanking internal transcribed spacers (ITS) within conserved regions of the 28S and 18S rRNA genes of all fungi (White et al. 1990). A portion of this reaction was then used as a template in a subsequent PCR using primer set Bd1a (5'-CAG TGT GCC ATA TGT CAC G-3') and Bd2a (5'-CAT GGT TCA TAT CTG TCC AG-3') (Annis et al. 2004) which amplified fragments of about 300 bp that included the 5.8S rRNA and flanking ITS regions of *Bd* (Annis et al. 2004). A *Bd*-positive DNA sample from a previous study (Gaertner et al., *in press*) and sterilized distilled water were used as positive and negative controls in all reactions, respectively.

Agarose gel electrophoresis (2% agarose in TAE buffer) (Sambrook et al. 1989) of the nested PCR revealed that 83% of the samples obtained in May were positive for *Bd*. None of the samples collected in July, however, tested positive for *Bd* even though the positive controls amplified. Individuals collected in July included one recapture (AD03, marked 3 using the method of Hero 1989) that tested positive for *Bd* in May. The clipped toe was almost fully healed and showed no evidence of regrowth. Additional toes were removed for the second *Bd* test, resulting in a new unique mark for this individual (8093; Hero 1989). In order to verify the detection of *Bd*, six randomly selected 300-bp-fragments were sequenced using the CEQ 8800 Quickstart Kit (5% DMSO added to the reaction mix) on a CEQ 8800 sequencer (Beckman Coulter, Fullerton, CA). These sequences (GenBank accession numbers FJ373880–FJ373885) were validated against the GenBank/EMBL databases using BLASTn (Pearson and Lipman 1988) and were identical to the published sequence of the 5.8S rRNA gene, and virtually identical to the published flanking ITS regions of *Bd* (AY997031). These data demonstrate *Bd* infection of large numbers of individuals of *A. c. blanchardi* in late spring (May), and absence of infection in the same population including a previously positive recapture in summer (July). Because sampling times differed with respect to basic environmental conditions (temperature and water availability), the data suggest seasonal effects of environmental conditions on the infection of *A. c. blanchardi* by *Bd*.

Seasonal variation in the prevalence of disease is not uncommon, as documented for several diseases of both humans and wildlife (Hosseini et al. 2004; Kriger and Hero 2007; Pascual and Dobson 2005). For *Bd,* significantly higher detection rates have been reported in winter than in summer (McDonald et al. 2005; Ouellet et al. 2005; Retallick et al. 2004). Kriger and Hero (2007) detected *Bd* infection in a population of stony creek frogs (*Litoria wilcoxii*) in up to 60% of samples collected in winter and spring, but at much lower rate (0–13%) in summer for the same population. As in our study, *L. wilcoxii* that were positive for *Bd* initially were shown to be negative for this pathogen upon subsequent recapture (Kriger and Hero 2006).

The effects of temperature on *Bd* are well documented in laboratory studies. *Bd* can grow *in vitro* in the lab from 6–28ºC, with an optimum at 23ºC (Longcore et al. 1999). Frogs in laboratory studies have shown large differences in susceptibility to the fungus as a function of temperature, with the highest mortalities occurring at 23ºC and with decreasing pathogenicity at higher temperatures (Berger et al. 2004; Lamirande and Nichols 2002). Infected frogs could be cured of *Bd* in the laboratory at temperatures above 32ºC (Johnson et al. 2003; Woodhams et al. 2003). The laboratory results suggest that the disappearance of *Bd* from the *A. c. blanchardi* population in the headwaters of Barton Creek during the season could very well be a function of increasing temperatures. However, currently we have no direct evidence for a causal relationship between the disappearance of *Bd* and higher temperature. Other seasonally variable environmental conditions such as microhabitat

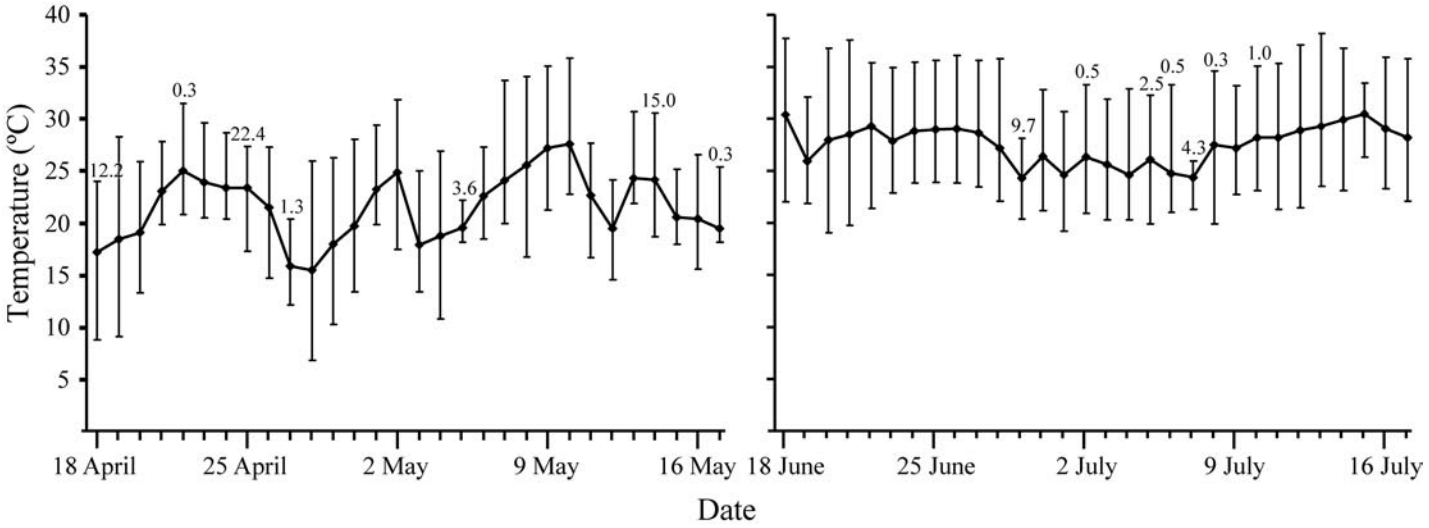

FIG. 1. Average temperature for each day with error bars showing the minimum and maximum daily temperatures for the 30 days preceding each sampling event (18 May and 18 July 2008) at the headwaters of Barton Creek near Dripping Springs, Texas, USA. Numbers adjacent to error bars depict total daily precipitation in millimeters.

temperature differences, relative humidity, and precipitation/water availability are closely related to temperature, and synergistic effects of these factors are difficult to quantify.

Although it is well known that *Bd* is spread via aquatic zoospores and prefers moist environments (Longcore et al. 1999; Ron 2005), a significant inverse relationship between precipitation and prevalence of *Bd* has been found (Kriger and Hero 2007). These authors acknowledge that this finding is counterintuitive to the life history of this pathogen, and suggest that this negative relationship may be an artifact of seasonal weather patterns in southeastern Queensland, Australia (warm wet summers, cool dry winters), with a positive relationship between precipitation and *Bd* infection being more the global norm. Our results support the latter hypothesis, in that *Bd* detection was 0% in the samples collected during drier conditions.

The overall pattern in *Bd* detection with respect to temperature is the same in our study as has been found in previous work in wild amphibian populations (e.g., Kriger and Hero 2007; decreasing prevalence of infection with increasing temperature). However, the mean 30-day temperature for our May sampling date (21.6ºC) was within the range of highest 30-day mean temperatures recorded in Kriger and Hero (2007). These authors found that *Bd* prevalence ranged from 0–13.3% when temperatures ranged from 19.5–22.2ºC, a temperature range that our data suggest could be optimal for infection in central Texas. This lack of concordance emphasizes the need for studies that carefully consider multiple environmental variables in examining seasonal variation in *Bd* prevalence within populations.

Our findings indicate that high temperature, drying of aquatic habitats, or an interaction between these factors may reduce *Bd* prevalence in semi-aquatic amphibians to very low levels in ecosystems characterized by hot, dry summers and/or ephemeral water sources. The diurnally active *A. c. blanchardi* sampled in this study may have been exposed to temperatures in excess of 30ºC (Fig. 2), approaching the thermal range known to cure *Bd* in laboratory studies (Johnson et al. 2003). This hypothesis might explain the decline of populations of *A. c. blanchardi* in the northern parts of the range where populations experience temperatures that are amenable to *Bd* for a much larger part of the year than further south where infections may be regularly cleared by higher temperatures and the lack of water which have both been suggested to limit the distribution of *Bd* (Skerratt et al. 2008).

Further research is necessary to determine whether the sharp declines in *Bd* prevalence observed in cricket frogs are mirrored in the entirely aquatic plethodontid salamanders that occur in the region, and thereby the utility of these frogs as a proxy or indicator of *Bd* in central Texas aquatic ecosystems.

Acknowledgments.—We are indebted to Texas State University (Research Enhancement Program Grant No. 2000021007), the Department of Biology, and the National Science Foundation (GK-12 grant No. 0742306) for financial support. The research was carried out in compliance to the rules overseen by the Texas State Institutional Animal Care and Use Committee (IACUC, permits 0817-05-059FD39E10_15 and 0819_0414_21), and with sampling authority from the Texas Parks and Wildlife Department (TPWD, permit SPR-1005-1515 and SPR-0890-234). We thank Alicia Diehl for allowing us access to the sampling location.

The Chytrid Fungus in the Red Salamander, *Pseudotriton ruber*, in South Carolina, USA

RICHARD R. MONTANUCCI
Department of Biological Sciences, Clemson University
Clemson, South Carolina 29634-0314, USA
e-mail: rrmnt@clemson.edu

The chytrid fungus, *Batrachochytrium dendrobatidis* (*Bd*), has been implicated in mass mortality, population declines, and apparent extinctions of anuran amphibians worldwide (Berger et al. 1998). To date, this pathogen has been detected in 233 of 422 (55%) anuran species in 17 of 25 families and 24 of 36 (67%) of caudate species in 5 of 5 families (Olson and Ronnenberg 2008). In South Carolina, USA, *Bd* has been detected in anurans at three locations (Daszak et al. 2005; Rothermel et al. 2008). Speare and Berger (2004) reported *Bd* in the Red Salamander, *Pseudotriton ruber*, in South Carolina from a personal communication (Donald K. Nichols, National Zoological Park, Washington D.C.). However, that record was listed erroneously under Salamandridae, and the specific region within South Carolina was not indicated. Herein, I report the details of the case and its significance.

On 12 March 2002, a female *Pseudotriton ruber* was collected while crossing SC Route 130, ca. 6.6 road km N of SC Route 11 (34.94606°N, 83.01564°W), Oconee County, South Carolina, USA. The salamander was returned to the laboratory and maintained alone in a plastic shoebox with paper towels and ca. 2.5 cm of water. The salamander was not fed, but weekly water changes were made. On 13 April 2002, multiple molts were noticed in the container. Unlike the shed skins of healthy salamanders that are a translucent white in color, these sheds were dark black. On 20 April, another water change was made, and again, at least one black molt was found. The salamander was inspected daily from 20–24 April, and continued to produce black molts. On 24 April it was found dead and was immediately preserved in 70% ethanol.

After consulting my laboratory notes, I found a second specimen of *P. ruber*, a small metamorph from near Oconee Station Falls (Station Cove Falls) (34.84933°N, 83.08531°W), Oconee County, South Carolina, that had displayed similar symptoms, e.g., frequent ecdysis in which the molts were dark in color. This specimen had been collected on 10 Sept 2001 and was euthanized and preserved on 24 Nov 2001.

On 8 May 2002, both specimens were sent to pathologist Donald K. Nichols at the National Zoological Park, Washington, DC, for histological examination. On 14 June 2002, I received word from Dr. Nichols concerning the two specimens. The small metamorph had scattered areas of mild inflammation of its epidermis, but there was no evidence of chytrid fungus. Samples of skin and internal organs had been taken from the large female. According to Nichols, there was nothing remarkable about the internal organs, but the epidermis had hyperkeratosis with an abundance of chytrid thalli. The case histories of two other *P. ruber* collected by me in adjacent Pickens County, South Carolina, suggested infection with chytrid fungus. However, the two specimens were not available for histological examination.

The Southern Appalachian region has long been recognized for its high salamander biodiversity (Bruce et al. 2000; Hairston 1949). To my knowledge, this is the first published report of chytridiomycosis in *Pseudotriton ruber* and represents the second caudate species known to be infected with this fungal pathogen from the Blue Ridge Physiographic Province of the Southern Appalachian Mountains. Rothermel et al. (2008) previously reported *Bd* in *Notophthalmus viridescens* from the Upper Tallulah River, in northern Georgia. The authors also sampled *Plethodon metcalfi* and *Desmognathus monticola* from near the Highlands Biological Station in western North Carolina; the two species tested negative for *Bd*. Additionally, Timpe et al. (2008) surveyed 19 frogs and 28 salamanders (including *P. ruber*) from five physiographic regions in Georgia; *R. clamitans, R. palustris*, and *R. sphenocephala* and *Desmognathus conanti* tested positive for *Bd*, but none of the positive sites were in the Blue Ridge Physiographic Province. My collection site for *P. ruber* is situated near the Jim Timmerman Natural Resources Area; the property is managed by the state of South Carolina and supports a diverse amphibian fauna (Montanucci 2006). The positive finding of *Bd* in *P. ruber* emphasizes the need to initiate a comprehensive survey of all amphibian species in the region for chytridiomycosis.

Acknowledgments.—I am grateful to Donald K. Nichols for histological examination of the two *P. ruber* specimens. Corey Roelke and Barbara Foster helped with field collecting. H. Lee Mitchell, South Carolina Dept. of Natural Resources, Clemson Office, provided the GPS information. I also thank Dede Olson for assistance with the manuscript preparation.

First Reported Detection of *Batrachochytrium dendrobatidis* in Florida, USA

CAROL E. RIZKALLA
Department of Education & Science, Disney's Animal Kingdom
PO Box 10000, Lake Buena Vista, Florida 32830, USA
e-mail: Carol.X.Rizkalla.-ND@disney.com

The fungal pathogen *Batrachochytrium dendrobatidis* (*Bd*) has been linked to amphibian population declines around the world (Daszak et al. 2003; Ron 2005). Within the United States, *Bd* appears to have high prevalence in western states and in the northeast (Longcore et al. 2007; Schlaepfer et al. 2007). Infected anurans also have been found throughout the southeast, but, to my knowledge, not as of yet, in Florida (Green and Dodd 2007; Peterson et al. 2007; C.K. Dodd, Jr., pers. comm.). Ecological niche modeling demonstrated high suitability for *Bd* in Florida, and very high suitability along the Lake Wales Ridge in central Florida (Ron 2005). Here, I report the results of surveys of 7 amphibian species on Walt Disney World's Wildlife Management and Conservation Area (WMCA).

The WMCA is a network of primarily forested wetlands with interspersed upland spanning 3380 ha in Orange and Osceola counties designed as a buffer area for Reedy Creek and managed by the Reedy Creek Improvement District (Fig. 1). The Reedy Creek basin includes a significant portion of the headwaters of the Kissimmee River. Sampling for this study was restricted to the northern portion of the WMCA, centered approximately at 28.39929703°N, 81.60801927°W. Amphibians were captured using plywood coverboards, minnow traps, and during incidental encounters. Seventeen coverboard arrays were placed 500 m apart with each array checked once a month. Ten minnow traps were placed in canals, marsh, and a pond for 3 days each month. Clean disposable gloves were worn when handling each animal. Live amphibians were swabbed along the ventral surface and legs 25 times with cotton-tipped swabs (Puritan, Guilford, Maine). Swab tips were stored at room temperature in 2-ml screw cap microcentrifuge tubes (Fisher #02-681-343) containing 1 ml of 70% ethanol. Because optimal pathogen growth in culture occurs at 23ºC (Daszak et al. 2003), sample collection was restricted to cooler months in Florida, November 2007–April 2008, to increase the probability of *Bd* detection, if present. Maximum daily temperature during sample days ranged from 17.8–29.4°C. Samples were sent in May 2008 to Pisces Molecular (J. Wood, Boulder, Colorado, USA) for analysis using a polymerase chain reaction to detect *Bd* presence (Annis et al. 2004).

Two additional samples were included in the analysis. One dead American Bullfrog tadpole (*Lithobates catesbeianus*, formerly *Rana catesbeiana*) was found in a minnow trap. The keratinized region around the mouth was submitted for analysis. An adult bullfrog (non-collection animal) was found in an exhibit within Disney's Animal Kingdom® Theme Park. It had abrasions on its snout and was brought to the veterinary hospital for treatment, where a swab sample was collected. The cause of the abrasions was unknown. The snout was medicated with Nolvasan® solution and the frog was released where it was found. None of the animals in this study exhibited clinical signs of infection by *Bd*.

FIG 1. Location of Walt Disney World Wildlife Management and Conservation Area, Florida, USA, where amphibians were sampled for presence of *Batrachochytrium dendrobatidis* (*Bd*). Dashed box indicates study area. *Bd*-positive sample locations are indicated by an X.

Although a representative sampling of all amphibian species was desired, samples were biased heavily towards Greenhouse Frogs (*Eleutherodactylus planirostris*) because they were the most abundant species underneath coverboards. Eighty-one samples

TABLE 1. Prevalence (no. animals testing positive/total sampled) of *Batrachochytrium dendrobatidis* in amphibians in Walt Disney World's Wildlife Management and Conservation Area, Florida, USA. Number of sites sampled indicates the number of coverboard and/or trap locations where species were encountered.

Species	No. sites sampled	Prevalence
Florida Cricket Frog (*Acris gryllus dorsalis*)	1	1/5
Southern Toad (*Anaxyrus terrestris*, formerly *Bufo*)	4	0/7
Greenhouse Frog (*Eleutherodactylus planirostris*)	10	0/59
Green Treefrog (*Hyla cinerea*)	2	0/6
Cuban Treefrog (*Osteopilus septentrionalis*)	1	0/1
American Bullfrog (*Lithobates catesbeianus*)	2	1/2
Two-toed Amphiuma (*Amphiuma means*)	1	0/1

from 7 species were submitted for analysis (Table 1). *Bd* was detected in the adult bullfrog found within Disney's Animal Kingdom® and one Florida Cricket Frog (*Acris gryllus dorsalis*) in the WMCA. This appears to be first detection of *Bd* in Florida. Due to small sample sizes and potentially low Bd prevalence rates, it is premature to rule out the presence of *Bd* in these other species.

This study has documented the occurrence of *Bd* in central Florida. *Bd* was not detected in northern Florida, despite extensive sampling (C. K. Dodd, Jr., pers. comm.), and few samples have been tested elsewhere in the state (D. Green, pers. comm.). *Bd* does not appear to have had a negative impact on the amphibian population in the central Florida region as evidenced by apparently stable populations and no observed die-offs. Bullfrogs are a likely carrier of *Bd* because they show resistance to infection, and may be important in the spread of the pathogen (Daszak et al. 2004). Bullfrogs are abundant in Florida; therefore, the presence of *Bd* in Florida is not unexpected.

Audio recordings suggest there are hundreds of Florida cricket frogs occupying the pond where the positive sample was found. With a small sample size, it is not known whether this is another species that is effectively resistant to infection by *Bd* (Woodhams et al. 2007); more testing is required. An alternative explanation is that this was an early detection within the population, because Northern Cricket Frogs (*A. crepitans*) and Blanchard's Cricket Frogs (*A.c. blanchardi*) are susceptible to infection (Pessier et al. 1999; Steiner and Lehtinen 2008; Zippel and Tabaka 2008). Monitoring of cricket frogs and species not yet tested at this site will continue. Continued monitoring for the presence of *Bd* in Florida is recommended. As most waters in Florida flow south towards the Everglades, monitoring for the presence of this disease in biologically-rich south Florida should be a priority, given its occurrence in central Florida and also in Cuba (Díaz et al. 2007).

Acknowledgments.—Members of Disney's Animal Programs, including V. Alford, A. Daneault, M. Hohne, T. Probst, and J. Sincage assisted in sample collection. D. Olson, A. Savage, J. Mellen, and S. Terrell provided useful comments on the manuscript. This study is in accordance with applicable institutional Animal Care guidelines and required state research permits were obtained. I gratefully acknowledge Disney's Animal Programs Cast Conservation Program for funding.

During the last two decades significant declines and extinctions of amphibians have been observed worldwide (Blaustein and Wake 1995; Houlahan et al. 2000; Stuart et al. 2004). The Neotropics are among the most impacted areas, with sudden losses of anuran species noticed during the 1980s in Costa Rica, Ecuador and Venezuela (Pounds and Crump 1994; Pounds et al. 1997; Young et al. 2001; Ron et al. 2003). Population declines and losses have been more significant at high elevation (above 1000 m) with one study showing all species of *Atelopus* with sufficient data (N = 28) declining and 75% disappearing (La Marca et al. 2005). A serious contributor to amphibian declines worldwide is the fungus *Batrachochytrium dendrobatidis* (*Bd*), which was present in the Neotropics before declines were noticed in the 1980's (Berger et al. 1999; Speare and Berger 2000; Bosch et al. 2001; Bradley et al. 2002; Lips et al. 2005; Ron and Merino 2000). *Bd* is now implicated as one of the causes of the extinction of several species of anurans from these regions (Ron et al. 2003; La Marca et al. 2005; Merino-Viteri et al. 2005). While *Bd* has been detected in amphibians from many high elevation sites in the Neotropics (e.g., Ron and Merino 2000; Young et al. 2001; Lips et al. 2003),

low elevation sites in the Neotropics have received comparatively little attention and thus reports on the detection of *Bd* at these sites are less common (Puschendorf et al. 2006; Oliveira de Queiroz Carnaval et al. 2006).

The aim of this study was therefore to examine the occurrence of *Bd* in amphibian species of a Neotropical lowland rainforest, i.e., at sites in the Upper Amazon Basin of eastern Ecuador at low elevation (about 200 m). This study included analyses of amphibians occupying ecological niches above the forest floor and shrub layers, specifically the mid- to upper canopy, because the upper strata of Amazonian rainforests plays an integral role in ecosystem function and data are missing for the interaction of *Bd* with amphibians in this important microhabitat.

Methods.—Samples were collected from sites surrounding Tiputini Biodiversity Station – Universidad San Francisco de Quito (0.6384694°S, -76.1490806°W, 217 m elev.), at the border of Yasuni National Park in the eastern lowlands of Ecuador (Fig. 1) during May–August of 2004 and 2006. The vegetation of the region has been defined as Amazonian Evergreen Lowland Forest, where annual rainfall averages 2425–3145 mm, temperature averages 25°C (range is 15°–38°C), and average humidity is 88% (Balslev et al. 1987; Blandin Landívar 1976; Duellman 1978). This area is part of the Napo refugium, a subset of the Amazonian system, and it is likely to represent some of the oldest undisturbed forests and greatest biodiversity in the system (Prance 1982). Amphibians from the forest floor and shrub layer were collected near the banks of the Rio Tiputini at elevations between 190–250 m during visual encounter surveys. Amphibians occupying higher strata were collected during bromeliad patch sampling following the procedure outlined by McCracken and Forstner (2008).

FIG. 1. Schematic presentation of the sampling site within the Yasuni National Park near Tiputini Biodiversity Station (TBS) – Universidad San Francisco de Quito, in the Upper Amazon Basin of eastern Ecuador used for collection of amphibians to be tested for infection by *Batrachochytrium dendrobatidis*.

Toe clips and skin from thigh muscle samples were used to test for the presence of *Bd* (Table 1). Samples were grouped into three categories (fossorial/forest floor, shrub/sub-canopy, and upper canopy) along the vertical axis based on historical and current collection locations for each species tested. Species placed in the fossorial/forest floor category are those which utilize subterranean habitat such as burrows and holes or typically occur amongst the forest floor leaf litter. Thirty-six individuals of 15 species in the order Anura were tested from the fossorial/forest floor category. The second category contains species which occupy the forest understory (shrub/sub-canopy). Whereas some of these amphibians may occasionally be found on the forest floor, they are most commonly found on low vegetation (< 2 m); a few animals which were tested and placed in this category have been found up to 4 m. Twenty-nine individuals of 12 species in the orders Anura and Caudata were tested from the shrub/sub-canopy category. The final category contains species found in the upper canopy occupying tank bromeliad habitat above 4 m (4–38 m). Twenty-one individuals of 4 species in the order Anura were tested from the upper canopy layer.

Water temperature was collected in three tank bromeliads of the species *Aechmea zebrina* located in the upper canopy of an emergent tree, *Parkia multijuga*, at 32, 34, and 35.5 m vertical height and within 2 m horizontal distance from the tree bole. One Thermochon iButton (model DS1922L) temperature logger was placed in an outer leaf bract of each bromeliad a minimum of 8 cm below the water level. Data loggers were set to collect water temperature every 30 minutes (35.5 m) and every 60 minutes (32 m, 34 m) at a resolution of 0.5°C with an accuracy of ±1°C from -30°C to +70°C. Duration of total data collection varied from 43 to 142 days from 31 March 2008 to 24 August 2008. Water pH was taken during bromeliad patch sampling according to McCracken and Forstner (2008) for five *A. zebrina* in each of 18 trees for a total of 90 bromeliads during field seasons in 2006 and 2008. An Oakton pHTestr 30 was used to collect water pH at a resolution of 0.01 pH with an accuracy of ±0.01 pH; a three-point calibration was performed before each tree sampled.

A nested PCR approach that has shown increased sensitivity of detection in samples with low template numbers and is outlined in detail in Gaertner et al. (*in press*) was used for detection of *Bd*. This approach used primers ITS1f (5'CTT GGT CAT TTA GAGC GAA GTA-3') and ITS4 (5'TCC TCC GCT TAT TGA TAT GC-3') targeting conserved regions of the 28S and 18S rRNA to amplify the 5.8S rRNA gene and the flanking internal transcribed spacer (ITS) of all fungi (White et al. 1990). PCR products from this reaction were purified and then used as a template for the subsequent PCR reaction using the *Bd*-specific primer set Bd1a (5'CAG TGT GCC ATA TGT CAC G-3') and Bd2a (5'CAT GGT TCA TAT CTG TCC AG-3') (Annis et al. 2004). The product from this reaction was examined by gel electrophoresis (2% agarose in TAE buffer) (Sambrook et al. 1989) for a fragment of approximately 300 bp (Annis et al. 2004). DNA from a sample positive for *Bd* from a previous study (Gaertner et al., *in press*) and sterilized distilled water were used as positive and negative controls, respectively. PCR products from samples showing the 300 bp amplicons were then sequenced using the CEQ 8800 Quickstart Kit with the addition of 5% DMSO to the reaction mix on a CEQ 8800 sequencer (Beckman Coulter, Fullerton, California). The sequences were

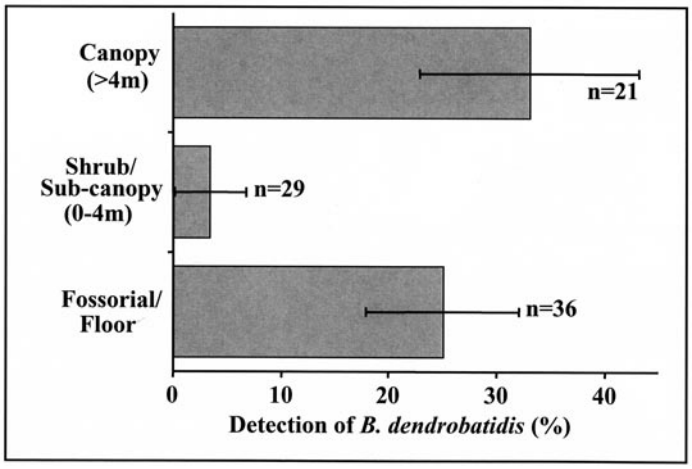

FIG. 2. Detection of *Batrachochytrium dendrobatidis* (% ± 95% confidence intervals, calculated in Microsoft Office Excel) in samples from amphibians collected within the Yasuni National Park, Ecuador, at three different vertical strata groups (fossorial/floor; shrub/sub-canopy, 0–4 m; and canopy, > 4 m).

validated against the GenBank/EMBL databases using BLASTn (Pearson and Lipman 1988).

Results.—Eighty-six amphibians of two orders (Anura N = 84, and Caudata N = 2) belonging to 7 families and 31 species were screened (Table 1) using nested PCR analysis (Gaertner et al., *in press*). Of those tested, 17 individuals (20%) representing eight species were positive for *Bd*. *Bd* was detected from within each of the strata, with the fossorial/floor group consisting of nine positive from 36 individuals tested (25%), shrub/sub-canopy group consisting of one positive from 29 tested (3%), and the canopy group consisting of seven positive of 21 tested (33%) (Fig. 2). Comparative sequence analysis of all 17 amplicons retrieved from PCR amplification with existing sequences of *Bd* available in GenBank/EMBL databases confirmed the detection of *Bd*. All sequences exhibited more than 99% similarity, with all sequences of the 5.8S rRNA gene being identical to the published sequence of *Bd* (AY997031), and those of seven amplicons displaying small differences in the ITS regions (Table 2).

Water temperatures recorded inside *A. zebrina* bromeliads at 32 m were 20.5–30.5°C (23.8 ± 1.9 [$\bar{x}$ ± SD], N = 1369), at 34 m they were 20.0–31.0°C (24.1 ± 1.9, N = 3422), and at 35.5 m were 20.5–32.5°C (24.5 ± 2.5, N = 2017). The mean pH recorded was 4.48 ± 0.67 (N = 90).

Discussion.—The presence of *Bd* was demonstrated in amphibians of the Upper Amazon Basin of eastern Ecuador. *Bd* has been detected from several high altitude sites in the Neotropics (Lips et al. 2003; Ron and Merino 2000; Young et al. 2001), however, detections at low elevation sites are less common (Oliveira de Queiroz Carnaval et al. 2006). Our results have shown that *Bd* is present in Amazonian lowland rainforests at elevations less than 300 m. This finding is significant because even though amphibian declines are not as prevalent at low elevations (Oliveira de Queiroz Carnaval et al. 2006; Puschendorf et al. 2006), *Bd* is present and could be contributing to declines. Amphibians may also be serving as a reservoir for *Bd* which could then move to and infect amphibians at higher elevation sites.

Another important finding of this study is the demonstration of clinical signs of chytridiomycosis and a positive detection for *Bd* by one individual (*Leptodactylus pentadactylus*) included in the study. In laboratory experiments, *Bd* grew best and was most lethal under cool (22ºC), moist conditions (Piotrowski et al. 2004; Woodhams et al. 2003) suggesting that montane species should be the most likely candidates for declines. This scenario is certainly supported by studies in the area with one study failing to find even a single apparently healthy population of *Atelopus* at elevations above 1000 m (La Marca et al. 2005). Despite the apparent virulence of *Bd* at high elevation sites, there are very few accounts of population declines caused by *Bd* infection at low elevations. The discovery of *L. pentadactylus* at this elevation showing clinical signs suggests that *Bd* might play a more important role in lowland declines than previously thought.

TABLE 1. Amphibian species collected from three vegetation strata (canopy, shrub/sub-canopy, fossorial/floor) in Yasuni National Park, Ecuador, and analyzed for *Batrachochytrium dendrobatidis* (*Bd*).

Amphibian species	Number of samples analyzed	Number of *Bd*-positive samples
Canopy		
Hypsiboas boans	1	0
Osteocephalus taurinus	4	0
Pristimantis aureolineatus	7	4
Pristimantis waoranii	9	3
Total	21	7
Shrub/sub-canopy

Accession Number	Difference
FJ232005	1 bp insertion at base 68 (A)
FJ232006	1 bp insertion at base 68 (A), deletion of positions 80–86
FJ232007	1 bp insertion at base 68 (A)
FJ232009	SNP at position 47 (G to T)
FJ232019	deletion of positions 13–20, SNP at position 55 (T to A)
FJ232020	deletion of positions 36–39, SNP at position 51 (A to G)
FJ232021	deletion of positions 31–33

All previous studies on *Bd* have used amphibians caught at or near ground level. This allows for testing of only the portion of amphibians contained in the lower strata of a structurally complex system. We detected *Bd* on amphibians inhabiting all strata of the forest which demonstrates that searches not including vertical strata may be lacking important data on the system. Furthermore, we found evidence that the occurrence of *Bd* infection on amphibians along a vertical axis is non-random in this system. Infection by *Bd* was found to be significantly higher in the fossorial/floor and canopy groups, showing 25% and 33% of individuals infected, respectively, than in the shrub/sub-canopy group with only one individual (3%) infected. Each of the strata of the rainforest has unique microclimate characteristics that could potentially affect *Bd* infections. In this case the availability of water may play a role in the prevalence of infection in each of the groups. Amphibians of the fossorial/floor group have water available in the form of streams and standing pools and the canopy group has access to water captured in phytotelmata, primarily tank bromeliads. Because *Bd* is transmitted via aquatic zoospores (Longcore et al. 1999), the absence of an abundance of standing water available to amphibians of the shrub/sub-canopy group may be reducing their exposure to the fungus. Previous studies have demonstrated that environmental conditions at the landscape level can have strong effects on host-pathogen dynamics (Woodhams et al. 2006), and future studies should include the investigation of interactions of *Bd* with environmental conditions, including water availability, on both the landscape and microhabitat level.

Environmental parameters for *Bd* have been found to have a significant influence on its pathogenicity (Andre et al. 2008; Piotrowski et al. 2004). Piotrowski et al. (2004) found isolates of *Bd* to grow and reproduce (in culture) between 4–25ºC and pH 4–8. Optimal growth of *Bd* zoospores occurred at temperatures of 17–25ºC and pH 6–7 (Piotrowski et al. 2004). Mortality rates in studies of *Bd*-infected frogs exposed to ambient temperatures of 17–25ºC have been >50%, although several studies show increased survival and decreased infection rates with temperatures >22ºC (Andre et al. 2008; Berger et al. 2004; Carey et al. 2006; Kriger and Hero 2007; Woodhams et al. 2003). Exposure to temperatures >25ºC has been shown to kill *Bd* zoospores and cure infected frogs (Berger et al. 2004; Kriger and Hero 2006; Piotrowski et al. 2004; Woodhams et al. 2003). While *Bd* prefers a near neutral pH, swimming zoospores were found in cultures at pH 4 and a temperature of 23ºC for 14 days (Piotrowski et al. 2004).

In our study, basic environmental water parameters collected from *A. zebrina* tank bromeliads indicate optimal temperature conditions for the persistence of *Bd* in the canopy. While pH levels were lower than previously reported as optimal conditions in fungal culture experiments, it remains unclear what effect this has *in situ*. *Pristimantis aureolineatus* and *P. waoranii* are known permanent inhabitants of *A. zebrina* bromeliads and with 44% of those individuals screened in this study testing positive it seems evident that *Bd* is present in canopy phytotelmata. However, definite proof of this assumption requires detection of *Bd* directly in water of the bromeliads. Many other species of anurans utilize bromeliad habitat for egg and tadpole deposition sites and may act as a reservoir for transferring the pathogen between sites. Several species of Dendrobatidae are of particular concern since they transfer tadpoles from terrestrial deposition sites to bromeliads in the canopy for final development. This broad traverse of habitats may facilitate the movement of *Bd* between terrestrial and canopy water sources, additional studies are needed to track potential movement of *Bd* along the vertical axis.

Four ecological traits are commonly associated with amphibian populations in decline including: aquatic mode of life, occurrence at mid to high altitudes, low fecundity and endemic distribution (Laurance et al. 1996; Lips 1998; Lips et al. 2003; Williams and Hero 1998). The observation of clinical signs of chytridiomycosis at a low elevation site and the characteristics of microhabitat utilized by permanent canopy anuran inhabitants infected by *Bd* demonstrate that the threat of chytridiomycosis may still be significant at sites even in the absence of those traits.

Acknowledgments.—We are indebted to the National Science Foundation (Graduate Research Fellowship Program (SFM), and GK-12 grant No. 0742306) for financial support. Funding was also provided in part by Texas State University–Department of Biology and the TADPOLE Organization. Specimens were collected under permit numbers 006-IC-FA-PNYRSO and 012-IC-FA-PNY-RSO, and exported under permit numbers 001-EXP-IC-FA-RSO-MA and 005-EXP-IC-FA-RSO-MA issued by the Ministerio del Ambiente, Ecuador. The research was carried out in compliance to the rules overseen by the Texas State Institutional Animal Care and Use Committee (IACUC, permits 0721-0530-7, 05-05C38ADFDB, and 06-01C694AF). We thank all the staff at the Tiputini Biodiversity Station – Universidad San Francisco de Quito, especially Jaime Guerra, David Romo, Kelly Swing, and Consuelo de Romo for coordinating logistical support, David Romo, Gonzalo Banderas, and Leo Zurita for help obtaining visas and research, collection, and export permits, Bejat McCracken, James Dixon, Josephine Duval, Paul Herbertson, Tana Ryan, and Robert Winters for field work assistance, and Diana McHenry and Michele Gaston for laboratory and sample management assistance.

NATURAL HISTORY NOTES

Instructions for contributors to Natural History Notes appear in Volume 40, Number 1 (March 2009, p. 66) and also are available online at: http://www.ssarherps.org/pages/HRinfo.php

CAUDATA — SALAMANDERS

AMBYSTOMA MACULATUM (Spotted Salamander). **OCCURRENCE.** *Ambystoma maculatum* is a wide ranging mole salamander found from Nova Scotia and southern Ontario through Georgia and eastern Texas (Conant and Collins 1998. Reptiles and Amphibians of Eastern/Central North America, 3rd ed., expanded. Houghton Mifflin, Boston, Massachusetts. 616 pp.). It is most commonly associated with lowland wetlands (Thompson and Gates 1982. Oikos 38:273–279.). In the 75+ years of ecological research at Mountain Lake Biological Station (MLBS, Salt Pond Mountain, Giles County, Virginia, USA, 37.37485°N, 80.52413°W, NAD 83; 1160 m elev.), this species has never been recorded (H. Wilbur and J. Murray, pers. comm.). Herpetological research over the last 20 years has included regular sampling of amphibian breeding locations; therefore, presence of this species without detection during the past two decades is highly unlikely.

A single adult male *A. maculatum* was captured at a drift fence surrounding Horton Pond on MLBS property on 6 April 2008 (mass = 16.31 g). It was captured exiting the pond on 12 April 2008. The drift fence was opened in May 2005 and has been run from March–October each year since. The 2007–2008 winter was mild in southwestern Virginia and this first capture *of A. maculatum* at MLBS might indicate that changes in weather conditions could make upper elevation ponds more conducive for this species. Observations such as these are important as researchers study the effects of climate change on the abundance and distribution of species.

CRYPTOBRANCHUS ALLEGANIENSIS ALLEGANIENSIS (Eastern Hellbender). **MULTIPLE CLUTCHES.** *Cryptobranchus alleganiensis alleganiensis* are unique in that unlike most salamanders, fertilization occurs externally, with males defending the nest until the eggs are hatched (Petranka 1998. The Salamanders of the United States and Canada. Smithsonian Inst. Press. Washington, DC. 587 pp.). Males typically establish nesting sites under large, flattened rocks and a female will enter the chamber to expel her eggs (Alexander 1927. Buffalo Soc. Nat. Sci. 7:13–18; Bishop 1941. The Salamanders of New York. New York State Mus. Bull. 324. Albany, New York; Nickerson and Mays 1973. The Hellbenders: North American "Giant Salamanders." Milwaukee Public Mus. Pub. Biol. Geol. 1:1–106). Smith (1912. J. Morphol. 23:61–157) observed that the number of eggs a female could lay in one season was limited, and that these would all be deposited at the same time. Based on the large number of eggs commonly observed in a nest, the variability of developmental stage of eggs in the same nest, and the noticeable difference in the color of eggs (which varies between females but is constant for eggs from one individual), Smith (1912, *op. cit.*) suggested that multiple females would lay their eggs in the same nest, to be fertilized and guarded by the attending male. Bishop (1941, *op. cit.*) also inferred joint clutches based upon a comparison of the number of eggs in females' ovaries with the total number of eggs commonly found in nests. To our knowledge, this is the first study to prove through genetic means that multiple females deposited eggs in a single nest.

On 15 Oct 2007, KML and JTB found a male *C. a. alleganiensis* guarding a nest of eggs in the Big Piney River, Missouri under a large rock. The eggs appeared to be from two different clutches due to developmental stages. Some of the eggs were beginning to hatch while others appeared to be several weeks from hatching. All of the eggs were removed and transported to Shepherd of the Hills Hatchery, Branson, Missouri to be hatched and captive-reared for future propagation. Eggs from one clutch hatched an average of 16 days earlier than those from the other clutch. This suggested that the eggs were laid at different times, and thus by two different females. Developmental time may be a suitable method of identifying eggs from multiple mothers, although simultaneous hatch dates would not reveal nest heterogeneity. In this case, genetic testing could provide insight into clutch maternity.

Polymerase chain reaction, with the universal primers L15926 and 12SAR-H, was used to amplify and sequence a 525bp fragment of the control region of the mitochondrial genome. Initial screening suggested that the larvae had two different haplotypes that varied by a single base pair difference. The two haplotypes corresponded to the two putative clutches. To confirm this interclutch variation, eleven additional larvae (five from one clutch and six from the other) were tested in a blind experiment. All eleven larvae exhibited one of the two previously observed haplotypes, providing correct assignment to their respective clutches.

Thus, based upon stage of development and genetic confirmation, we have documentation of the deposition of clutches by multiple female *C. a. alleganiensis* in a single male nest. To investigate the possibility of multiple paternities in a single nest site, microsatellite profiles are being developed to identify males in the general locality.

This work was funded by the Missouri Department of Conservation. We thank numerous Missouri Department of Conservation staff at Shepherd of the Hills Hatchery for care of the eggs and larval hellbenders. Research was conducted in compliance with applicable animal care guidelines and appropriate permits were obtained.

DESMOGNATHUS FUSCUS (Northern Dusky Salamander). **ALBINISM.** On 3 July 2007, I collected a xanthic *Desmognathus fuscus* along Dead Stream east of Boyd Lake, Orneville, Piscataquis County, Maine, USA (catalogued into the Yale Peabody Museum as YPM A12540). The specimen measured 51 mm SVL and 104 mm TL. In life its color was a light yellow-orange, similar to those illustrated from Connecticut (Klemens 1993. Amphibians and Reptiles of Connecticut and Adjacent Regions. State Geological and Natural History Survey of Connecticut Bull. No. 112. 318 pp.) and Quebec (Desroches and Rodrigue 2004. Amphibiens et Reptiles du Quebec et des Maritimes. Editions Michel Quintin, Waterloo, Quebec. 288 pp.). Xanthic or so-called "yellow albino" specimens of *D. fuscus* have also been reported from West Virginia (Channell and Valentine 1972. J. Herpetol. 6:144–146) and Massachusetts (Tyning 1977. Herpetol. Rev. 8:118), and a leucistic larva was reported from Maryland by Harris (1970. Bull. Maryland Herpetol. Soc. 6:21–27; cited in Dyrkacz 1981. Recent Instances of Albinism in North American Amphibians and Reptiles. SSAR Herpetological Circular No. 11. 31 pp.). This is the first report of such an individual from Maine. During a brief survey at the collection site, I also observed a single typically pigmented (i.e., nearly black) *D. fuscus*, as well as ten *Eurycea bislineata*. All, including the xanthic individual, were found under rocks at the edge of the stream.

HEMIDACTYLIUM SCUTATUM (Four-toed Salamander). **DISTANCE FROM NESTING SITE**. *Hemidactylium scutatum* is a terrestrial salamander that inhabits deciduous and mixed forests of northeastern North America. Females migrate to nesting sites in early spring just before ovipositing. Nesting sites can vary in appearance, but sphagnum/mosses clumps hanging over small vernal pools are characteristic (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press. Washington, DC. 587 pp.). In every case that we studied, the nesting site was of small dimension, not locatable using 1:50000 nor 1:20000 maps, but they can easily be mapped in the field as a nesting polygon using GPS locality data. Working on conservation of this "special concern" species in the province of Québec (Canada), we need to know how far from the nesting site, in the surrounding terrestrial system, should we protect *H. scutatum*. Considering the lack of such information, we searched for individuals in the vicinity of nesting polygons, just before oviposition (early spring) or during fall and measured the distance between the individual and the periphery of the nesting polygon. We report our 11 measurements below to share this information and promote similar works, as it is essential to protect a portion of the terrestrial habitat surrounding nesting site to ensure local conservation of this species.

A: August 2001, Parc de la rivière Batiscan (46.6°N, 72.6°W), sex unk., 32 m; B: 8 Sept 2001, Tourbière de Saint-Narcisse (46.6°N, 72.6°W), sex unk., 25 and 72 m (individual nearby 2 known nesting polygons); C: 11 May 2002, Québec City (46.75°N, 71.316°W), female, 15 m; D: 21 April 2005, Québec City (46.75°N, 71.316°W), female, 41 m; E: 21 April 2005, Québec City (46.75°N, 71.316°W), female, 41 m; F: 21 April 2005, Québec City (46.75°N, 71.31666°W), female, 20 m; G: 26 August 2007, Trois-Rivières (46.316°N, 72.65°W), sex unk., 45 m; H: 10 Sept 2007, Trois-Rivières (46.316°N, 72.65°W), male, 11 m; I: 10 Sept 2007, Trois-Rivières (46.316°N, 72.65°W), male, 10.5 m. J: 11 Sept 2007, Trois-Rivières (46.316°N, 72.65°W), male, 5.5 m. Mean distance from nesting polygon: 33.6 m SD = 18.8 m. All GPS locality data were collected using the datum NAD 83.

LYCIASALAMANDRA LUSCHANI FINIKENSIS (NCN). **HABITAT AND ALTITUDE.** Two adult and two juvenile individuals *Lyciasalamandra luschani finikensis* were located on the central Gölcük Tepesi (36.3°N, 30.08333°W; WGS 84; 800 m elev.) northwest of Finike, southwestern Turkey, on 20 Feb 2007 at 1400 hr. The weather was cloudy, air temperature was 16ºC. Individuals were found under stones. The habitat was characterized by a dense mixture of maquis (*Arbutus arachne* and *Quercus coccifera* dominated) and *Cedrus libani*. The occurrence of this subspecies was previously reported from 750 m elev. at an inland location near Arif, where the habitat is dominated by dry maquis and *Pinus brutia* (Veith et al. 2001. Zool. Middle East 22:67–82). Previously, the occurrence of *L. l. finikensis* in a dense maquis-*Cedrus libani* dominated vegetation community was unknown. This locality also represents an altitude record for the subspecies. The occurrence of *L. l. finikensis* is known south (were it occurs at sea level in coastal maquis) and north of Finike (Veith et al. 2001, *op. cit.*) at the base of the Gölcük Tepesi, which consists of karstic limestone, similar to the entire southern Lycian area. Therefore, *L. l. finikensis* might be expected to occur along the entire mountain chain northward from Finike to Arif (Veith et al. 2001, *op. cit.*).

Submitted by **WOUTER BEUKEMA**, Apollo 10, 5591 PP Heeze, The Netherlands (e-mail: wouter.beukema@wur.nl); **PHILIP DE POUS**, Wiardastraat 5, 8934 AP Leeuwarden (e-mail: phillip.depous@wur.nl); and **PETER BRAKELS**, Luciastraat 7, 5821CL Vierlingsbeek, The Netherlands (e-mail: peter2.brakels@wur.nl).

PHAEOGNATHUS HUBRICHTI (Red Hills Salamander). **RECORD SIZE**. On 2 Dec 2007 at 0515 h, we captured a large adult female *Phaeognathus hubrichti* on a mesic hillside in Monroe County, Alabama (exact locality withheld), which measured (anesthetized) 135.19 mm SVL and 268.15 mm total length (19.72 g). This salamander exceeded the previous maximum size for *P. hubrichti* reported by Schwaner and Mount (Auburn Univ. Museum 11381; 134 mm SVL; 256 mm total length; Copeia 1970. 1970:571–573). *Phaeognathus hubrichti* is a federally threatened species, and therefore the salamander was photographed, received a Passive Induced Transponder (PIT tag), and was released at its home burrow.

Submitted by **SEAN P. GRAHAM** (e-mail: grahasp@auburn.edu), **SHANNON K. HOSS**, and **JAMES C. GODWIN,** Auburn University, Department of Biological Sciences, 331 Funchess Hall, Auburn, Alabama 36849, USA.

PHAEOGNATHUS HUBRICHTI (Red Hills Salamander). **LEUCISM**. On 19 Oct 2007 at 1900 h, on a mesic hillside in Monroe County, Alabama, USA (exact locality withheld), we captured a leucistic adult female *Phaeognathus hubrichti* (121.55 mm SVL; 113.2 mm TL). This is the first report of an aberrant color morph in this narrowly distributed genus. This individual lacked integumentary pigment and appeared pink overall (Fig. 1). Iris pigmentation was present. This individual appeared gravid based on the presence of enlarged follicles clearly visible through the body wall. We have observed and/or captured > 150 individuals at this site with typical pigmentation, indicating a low prevalence of these morphs in the population. The salamander was processed, photographed, received a Passive Induced Transponder (PIT tag), and returned to its home burrow.

FIG. 1. Leucistic female *Phaeognathus hubrichti* (top) compared to a typically-colored female.

Submitted by **SEAN P. GRAHAM** (e-mail: grahasp@auburn.edu), **SHANNON K. HOSS**, and **JAMES C. GODWIN,** Auburn University, Department of Biological Sciences, 331 Funchess Hall, Auburn, Alabama 36849, USA.

PLETHODON ALBAGULA (Western Slimy Salamander). **DIET**. On 22 March 2008, cave cricket (*Ceuthophilus* spp.) exit counts were performed using a red light at a cave entrance (Flintridge Cave, Travis County, Texas, USA) for two hours immediately following sunset, which occurred at 1944 h. At 2005 h I noticed the front portion of the head of a *Plethodon albagula* emerging from under a ledge near the cave entrance. I observed the salamander slowly ease out from under the ledge to capture cave cricket nymphs as they exited the cave. After each capture the salamander retreated to the crack and would remain there until another cricket nymph passed close to the ledge. At no time did the salamander emerge farther than one body length out from under the ledge. After about one hour of feeding on cricket nymphs the salamander retreated into the crack beyond view and did not come out again during the observational period, which ended at 2145 h.

PLETHODON CINEREUS (Eastern Red-backed Salamander). **COLORATION**. Two common color morphs are known for *Plethodon cinereus*. In the striped morph a straight-edged reddish stripe extends from the base of the head down the trunk to the tail. Dark gray or black borders the dorsal stripe on both sides. In some individuals the stripe may be orange, tan, yellow, or light gray. The unstriped morph, often referred to as the "leadback" phase, is dark gray or black on the back and sides. Some individuals may have brassy or silver flecking. The ventral surface is mottled with white and gray. There is usually more white than gray. A third color morph, the erythristic phase, lacks any dark pigment. Its back and sides are bright red and its ventral surface is white. The erythristic phase is known from scattered localities in the northeastern United States and southeastern Canada (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Inst. Press, Washington D.C. 587 pp.). It has been reported from eight counties in northeast Ohio (Pfingsten and Downs [eds.] 1989. Salamanders of Ohio. Ohio Biol. Surv. Bull. New Series 7:2, Columbus, Ohio, 315 pp.).

On 13 April 2007 an adult amelanistic *P. cinereus* was collected from beneath a limestone rock in a second growth deciduous woodlot along Greenville Creek in Darke County, Ohio, USA (40.14134°N, 84.78422°W; WGS 84). Dyrkacz (1981. Recent Instances of Albinism in North American Amphibians and Reptiles. SSAR Herpetol. Circ., No. 11) discussed a *P. cinereus* collected in Maryland but did not distinguish it as albino or one of the five other degrees of albinism he described. In this individual the top of the head, the limbs, sides, the underside, and other surfaces that typically are black or gray were pink with white flecks. The dorsal stripe was evident and rather than the reddish color typical of the striped color morph, it was salmon in color and extended from the nape to ca. 1/3 the length of the tail where it faded to the pink color of the rest of the body. The pupils reflected red in the flash of a camera. Color photographs of the specimen have been accessioned into the Herpetological Photodocumentation Collection at the Cincinnati Museum Center (CMC HP 441–447). Other *P. cinereus* found at the site were all the redback phase. I thank Greg Lipps Jr. for reviewing this note.

PLEURODELES WALTL (Spanish Ribbed Newt)**. ALBINISM**. The genus *Pleurodeles* ranges over North Africa and the Iberian Peninsula, whereas *P. waltl* is restricted to the Iberian Peninsula and western Morocco (Carranza and Arnold 2004. Syst. Biodiversity 1:327–337). This is the most common newt in the Iberian lowlands, where it inhabits both natural and artificial ponds (Salvador and García-París 2001. Anfibios Españoles. Canseco Eds. Talavera de la Reina. 269 pp.). The usual color is an olive green, brown, or yellowish grey spotted pattern. The yellowish, pink, or orange-colored belly also may show grey spots (Salvador and García-París 2001, *op. cit.*). Larvae show a grey or brown dark body with small black spots and greenish or metallic gleams (Díaz-Paniagua and López-Jurado 1981. Bol. Est. Cent. Ecol. 10:27–34).

An albino larva, 43 mm SVL and 82 mm TL, was captured on 19 April 2006, in a semi-natural permanent pond in Santa Marta

village (Albacete, Spain; 39.14944°N, 2.29027°W, ED50 datum; 740 m elev). The pond is almost circular with an average diameter of 45 m. Non-irrigated agricultural lands surrounds the pond and natural Mediterranean shrubland can be found 800 m distant. Aquatic vegetation was abundant, but shoreline vegetation was absent. Overall coloration of the larva was soft pink and the muscular bands were visible along the body. The caudal crests were transparent and the eyes were red.

Records of true albinism have not been reported in *P. waltl*. It has been twice described for this species (Fontanet et al. 1992. Herpetol. Rev. 23:79; Schreitmüller 1934. Zool. Anz. 108:95), although these records should be classified as partial albino or hypomelanistic specimens (Bechtel 1995. Reptile and Amphibians Variants. Colors, Patterns and Scales. Krieger Publ. Co., Malabar, Florida. 206 pp.; Rivera et al. 2001. But. Soc. Cat. d'Herp. 15:59–75). This is the first record of true albinism in the genus and the species.

The albino individual was found two weeks later showing abnormal behavior and died in the following hours. Death could be due to the high levels of solar radiation in the pond together with the absence of melanin. The specimen is deposited in the Centro de Rescate de Anfibios y Reptiles, Alcalá la Real, Spain (ref. 19/10/06-06)

ANURA —FROGS

ACRIS GRYLLUS (Southern Cricket Frog). **PREDATION**. A variety of arthropods are known to capture and feed upon anurans. A recent review (Toledo 2005. Herpetol. Rev. 36:395–400) made available an exhaustive list of arthropod predators and their anuran prey. According to this review, only one spider (*Dolomedes* sp.) has been documented to feed on *Acris gryllus*. On 20 Sept 2007 at 1920 h, a movement attracted our attention to the substrate of a large drying beaver pond in Tuskegee National Forest, Macon County, Alabama, USA (32.43014°N, 85.64678°W; WGS 84). For the next few minutes we witnessed a large *Dolomedes triton* grasping and attempting to subdue an adult male *A. gryllus* (Fig. 1). Both animals were captured and preserved. It is assumed that the spider would have successfully fed upon the frog. The spider's identification was made by D. Folkerts and confirmed by N. Burkett-Cadena (deposited in the Auburn Univ. Insect Museum). The *A. gryllus* was verified by C. Guyer and deposited in the Auburn University Museum (AUM 37607). Although this genus of spider was noted to feed upon *A. gryllus*, the species was not identified by Goin (1943. Proc. Florida Acad. Sci. 6:143–153). *Dolomedes* is a common genus throughout the Northern Hemisphere and is known to feed upon other small anurans including *Hyla cinerea*, *H. japonica*, *H. minuta*, and *Pseudacris feriarum* (Toledo 2005, *op. cit.*).

We thank D. Folkerts and N. Burkett-Cadena for identifying the spider, and C. Guyer for assistance on this note. This observation was made while conducting research funded by NIH grant R01-A149724 under ADCNR Permit 4268.

ATELOGNATHUS PATAGONICUS (NCN). **AQUATIC HABITAT.** An improved understanding of the aquatic ecology of semi aquatic amphibian is not only important from a conservation perspective, but it is vital to our understanding of population dynamics. *Atelognathus patagonicus* is an endemic frog to an endorrheic wetland system in Laguna Blanca National Park and surroundings, Northwest Patagonia, Argentina (Cei and Roig 1968. Physis 27:265–284; Gallardo 1962. Neotropica 8:45–68). Two morphological forms have been described for *A. patagonicus*: an "aquatic form" which has large interdigital membranes, highly developed cutaneous folds on its trunk and thighs, and a "littoral form" with fewer of these features (Cei and Roig 1968, *op. cit.*). For this semi-aquatic frog few data are available regarding its biology (Cuello 2002. Licenciature thesis, Universidad Nacional del Comahue, Bariloche, Argentina. 87 pp.; Fox et al. 2005. Copeia 2005:920–928) and no data regarding habitat use and activity are available, especially in areas where macrophytes are abundant.

The frog is now extinct in Laguna Blanca as a result of unauthorized introductions of predatory fishes (two trout species, *Oncorhynchus mykiss* and *Salmo trutta,* and *Perichthys colhuapiensis*). Currently the known distribution is restricted to 21 neighboring water bodies (between 0.5 ha and 60 ha), smaller than Laguna Blanca (1780 ha). Because of its extinction from Laguna Blanca, the species was listed as Endangered (IUCN, Conservation International, and Nature Serve. 2004. Global Amphibian Assessment. <www.globalamphibians.org> 13 Dec 2004). Also, with the introduction of perch in Laguna Blanca, limnological changes have been observed including: i) a drastic decrease of birds, and ii) a reduction of macroinvertebrates and macrophyte cover (largely *Myriophyllum quitense*). All of these changes have resulted in changes to the habitat complexity (Ortubay et al. 2005. Aquatic Conserv. Mar. Freshw. Ecosyst. 15). The objectives of our study

were to determine: 1) habitat use of *A. patagonicus* in areas with abundant macrophytes, and 2) the distribution of *A. patagonicus* at different depths in the lagoon.

This study was carried out during January, February, and April 2005 at a permanent lagoon, Laguna Verde, in Laguna Blanca National Park (39.00777°S, 70.38527°W; WGS 84, elev. 1250 m). The lagoon has a 17 ha surface and a 1.70 km perimeter, and constitutes an aquatic ecosystem with high abundance and diversity of aquatic birds including Andean Flamingo, Black-necked Swan, and grebes. These birds depend on the macrophyte vegetation (largely *M. quitense*) for food and nesting. The predation by grebes of larval and postmetamorphic *A. patagonicus* in the deeper vegetated area has been reported (Cuello et al. 2005. Herpetol. Rev. 36:298).

Frogs were captured with aquatic funnel traps (11 cm diameter, 30 cm long), one plastic funnel and a rubber band (Smith and Retting 1996. Herpetol Rev. 27:190–191) placed at three different depths: surface (20 cm), middle (70 cm) and maximum depth (ca. 350–450 cm), in vegetated and non-vegetated areas. Fifteen traps were set for 12 h during the night during Jan, Feb, and April at three different depths. Amphibian larvae and postmetamorphic individuals were collected; the tadpole stage (Gosner 1960. Herpetologica 16:183–190) and postmetamorphic body length were recorded. All individuals were returned unharmed to the original place of capture.

Atelognathus patagonicus was found at all water depths sampled. During the study we captured 85 *A. patagonicus*: 83 tadpoles (stage 28–39), one juvenile, and one "aquatic form" female. The captures were more abundant in vegetated areas (N = 74; mean/per trap = 3.5 ± 1.49) than in non-vegetated areas (N = 11; mean/per trap = 0.45 ± 0.15). Significant differences were found in the number of individuals by strata (Kruskal-Wallis, $H_2 = 7.14$, $p = 0.0281$). The difference was between the deeper and the middle strata (Dunn's test, $p < 0.05$). No differences were found in the number of individuals captured per month (Kruskal-Wallis, $H_2 = 1.99$, $p = 0.370$). The "aquatic form" female (body length = 4.5 cm) was found at 4.5 m in an area with a high abundance of *M. quitense*.

Our preliminary results show that larval and postmetamorphic *A. patagonicus* select deeper areas of the lagoon. The larger captures in deeper zones characterized by presence of aquatic vegetation suggest that the frog prefers *M. quitense* as refuge and/or as foraging habitats. According to our results, the resulting extinction of *A. patagonicus* at Laguna Blanca would be associated with the disappearance of *M. quitense* and also by the predation pressure and competition imposed by the presence of introduced fishes (Cuello et al. 2006. Phyllomedusa 5[1]:67–76; Cuello and Perotti, unpubl. data).

BOMBINA VARIEGATA (Yellow Fire-bellied Toad). **MATING BEHAVIOR**. Various authors have provided evidence for male toads attempting to amplex male conspecifics (Marco et al. 1998. Anim. Behav. 55[6]:1631–1635; Marco and Lizana 2002. Ethol. Ecol. Evol. 14:1–8), as well as for interspecific amplexus (Brown 1977. J. Herpetol. 11:92–94; Reading 1984. J. Zool. (Lond.) 203:95–101; Marco and Lizana 2002, *op. cit.*) and even for amplexus between males and inanimate elastic objects of similar size to a female toad (Ishii and Itoh 1992. Gen. Comp. Endocr. 86:36–42). However, evidence for males amplecting dead females is sparse. Herein I report the first record of a male *Bombina variegata* amplecting a dead female.

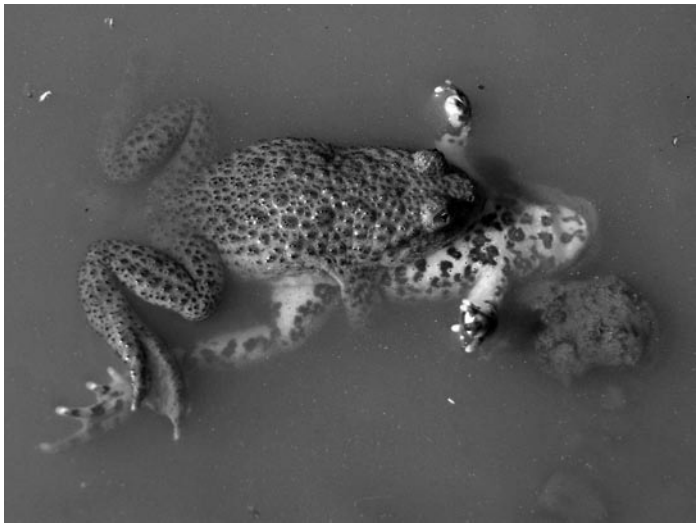

FIG. 1. Male *Bombina variegata* in amplexus with deceased female conspecific, Bukovec Mountains, Slovakia.

On 10 June 2008 at ca. 1630 h, I observed a male *Bombina variegata* in amplexus with a dead female conspecific in a wheel-rut temporary pond in the Bukovec Mountains, northeastern Slovakia (49.0872°N, 22.4086°E; WGS 84; 680 m elev.). The amplexus was inguinal, typical for the family Bombinatoridae, however the female was upside down, with the male on the female's belly rather than on her back (Fig. 1). The amplexus was observed for 5 minutes, during which time the male was immobile. When disturbed (slight pushes on the back), it swam away with difficulty for a total distance of ca. 30 cm without releasing the female. The pair was then separated and the female examined. The female's tongue was protruding out of its mouth, but no external damage was apparent and the cause of death was not determined. Although it is possible that death occurred during amplexus, this seems unlikely given the position of the female, suggesting that the male clasped the already-dead female.

This observation provides additional evidence suggesting that male *B. variegata* do not assess females carefully before clasping them, occasionally making obvious mistakes. The benefits of being first to encounter a female probably outweigh the costs of this type of error.

BUFO DEBILIS (Green Toad). **BREEDING HABITAT SELECTION.** Breeding site selection in *Bufo debilis* is poorly understood beyond the general knowledge that they use temporary, fishless water sources including desert playas, earthen stock tanks, and any other depressions that will temporarily hold water. Herein, I report

breeding pond selection by *B. debilis* in southwestern rangelands as modified by livestock use.

I made observations of *B. debilis* calling at ephemeral pools in an arid southwestern desert in southern New Mexico, west of Las Cruces. The survey area was in the Chihuahuan Desert on Bureau of Land Management grazing allotment 3013. During the monsoon season, approximately July 1 through late August, I surveyed earthen livestock tanks and desert playas for breeding amphibians. I conducted amphibian vocalization surveys between 2200 and 0200 h in areas that received rain that day or the previous day. Most available breeding sites on these allotments are livestock watering tanks that dry up on a yearly basis and were dry in the spring of 2007. I did not find *B. debilis* at tanks that received heavy livestock use as measured by the cover of livestock feces within 10 m of the earthen tank high water line. However, while surveying at three of these heavily used tanks I detected *B. debilis* calling from small ephemeral sites located remotely from the tank. Upon investigation, I found *B. debilis* males calling from seven small pools of water associated with washes or erosion sites created by wildlife and cattle trails. As described below, these small wetlands desiccated much more quickly than the larger tanks, but they may not have received as much livestock use as the larger tanks.

The first earthen cattle tank, Marijuana Tank contained no calling amphibians on 21 July 2007 or on any other survey day (32.40060°N, 107.11543°W; WGS 84; elev. 1402 m) (30 × 40 × 1.25 m deep). The tank water, measured with a Hydrolab MS 5 (Hach Environmental), had pH 7.42, 41.2% dissolved oxygen (DO), turbidity of 125 NTU , salinity of 0.14 ppt , and conductivity of 0.2973 mS/cm. This tank retained water into the fall. Three temporary sites close to the tank had calling amphibians including *B. debilis*. The first small wetland close to Marijuana Tank had ca. 20 calling *B. debilis* males (071) (32.40148°N, 107.12139°W; WGS 84; elev. 1408 m) (1 × 3 × 0.75 m deep). The wetland had pH 8.41, 23.3% DO, turbidity of 1969 NTU, salinity of 0.06 ppt, and conductivity of 0.1424 mS/cm, and retained water past 15 Aug 2007. The second small wetland close to Marijuana Tank had ca. 5 calling males (072) (32.40060°N, 107.11987°W; WGS 84; elev. 1407 m) (3 × 4 × 1.0 m deep). The wetland had a pH 8.43, 23.0% DO, turbidity of 1899 NTU, salinity of 0.06 ppt, and conductivity of 0.1424 mS/cm, and dried before 15 August 2007. The third site close to Marijuana Tank had ca. 50 calling males (073) (32.40203°N, 107.11522°W; WGS 84; elev. 1401 m) (2 × 4.5 × 1.25 m deep). The wetland had a pH 8.56, 21.8% DO, turbidity of 1463 NTU, salinity of 0.07 ppt, and conductivity of 0.1645 mS/cm, and was almost completely dry by 15 August 2007.

The second earthen cattle tank was unnamed, contained no calling amphibians 21 July 2007 or on any other survey day and retained water past September 2007 (32.39798°N, 107.11569°W; WGS 84; elev 1419 m) (15 × 20 × 1.25 m deep). I did not record measurements of water quality at this set of wetlands. Two small temporary water bodies close to the tank had calling amphibians including *B. debilis*. The first small wetland close to the unnamed tank had ca. 5 calling males and retained water until late August (74/82) (32.41933°N, 107.09922°W; WGS 84; elev 1432 m) (1 × 4 × 1 m deep). The second water body close to the unnamed tank had 4 calling males and dried by 15 August 2007 (070) (32.41933°N, 107.09922°W; WGS 84; elev 1432 m) (1 × 3 × 0.75 m deep).

The third cattle tank, North Kimbel, contained no calling amphibians 29 July 2007 or on any other survey date (32.33181°N, 107.07601°W; WGS 84; elev. 1396 m) (60 × 30 × 2.0 m deep) (Fig. 1 A). The tank water had a pH 8.62, 76.3% DO, turbidity of 1316 NTU, salinity of 0.17 ppt, and conductivity of 0.3535, and retained water past September 2007. Two temporary water bodies close to the tank had calling amphibians including *B. debilis*. The first site close to North Kimbel Tank had ca. 40 calling males (077)(32.33132°N, 107.07897°W; WGS 84; elev. 1394 m) (1 × 4 × 1.0 m deep) (Fig. 1 B). The wetland had a pH 7.71, 20.2% DO, turbidity of 2447 NTU, salinity of 0.08 ppt, and conductivity of 0.1882 mS/cm, and was dry by 16 August 2007. The second wetland close to North Kimbel Tank had ca. 20 calling males (079) (32.33132°N, 107.07885°W; WGS 84; elev. 1395 m) (1 × 3 × 1.0 m deep). The water had a pH 7.68, 24.7% DO, turbidity of 2945 NTU, salinity 0.08 ppt, and conductivity of 0.1858 mS/cm, and dried before 15 August 2007.

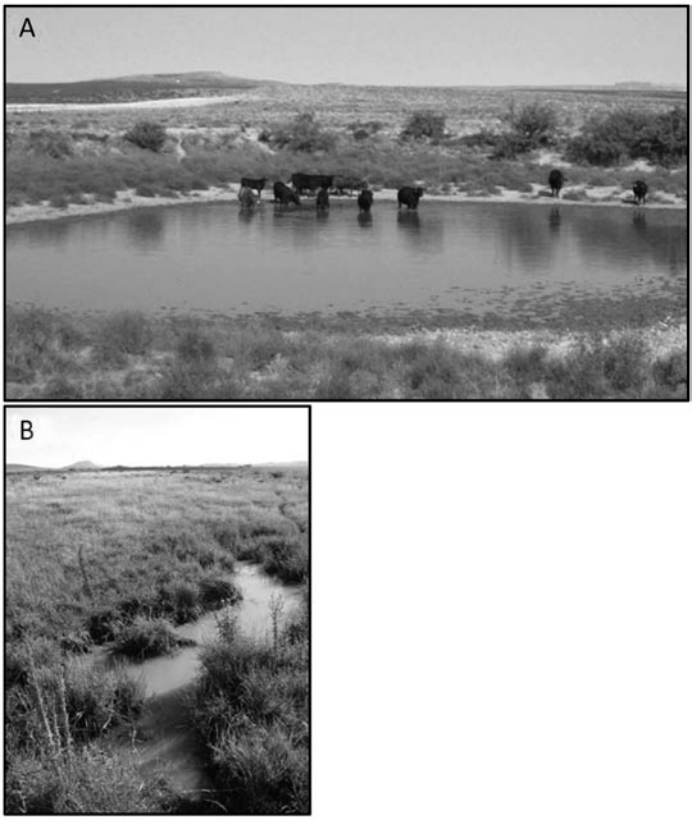

FIG. 1. Calling *Bufo debilis* were not detected at (A) North Kimbel livestock tank, which receives heavy livestock use; however, male *B. debilis* were calling from (B), a small ephemeral wetland created by erosion in a wildlife and livestock trail. These sites are 283 m apart, west of Las Cruces, New Mexico, USA.

Submitted by **KERRY L. GRIFFIS-KYLE**, Department of Fishery and Wildlife Sciences, New Mexico State University, PO Box 30003, MSC 4901, Las Cruces, New Mexico 88003, USA; e-mail: kerrygk@nmsu.edu.

BUFO FOWLERI (Fowler's Toad). **DIET**. It is well known that larval toads will consume injured, dead (Heinen and Abdella 2005. Am. Midl. Nat. 153:338–347), and live conspecifics (Bragg 1964. Herpetologica 20:17–24; Fox 2008. Herpetol. Rev. 39:151–154).

The increased nutrient uptake that results from larval grazing on moribund cohorts and conspecific carcasses is advantageous because it facilitates rapid larval growth and metamorphosis (Heinen and Abdella 2005, *op. cit.*). In *Bufo americanus* this process is probably triggered by chemical cues associated with decomposition of dead conspecifics and is more likely a form of scavenging than cannibalism (Heinen and Abdella 2005, *op. cit.*).

Though rare, isolated cases of active interspecific cannibalism have been documented in non-invasive (i.e., excluding cases of cannibalism in *B. marinus*), non-larval *Bufo*. To the best of our knowledge, non-larval conspecific scavenging and active conspecific cannibalism is unknown in *B. fowleri*. In fact, larger *B. fowleri* can apparently differentiate between the movements of invertebrate prey and newly metamorphosed toadlets, thus avoiding active conspecific cannibalism (Clarke 1974. Am. Midl. Nat. 91[1]:140–147). Additionally, Klimstra and Myers (1965. Trans. Illinois Acad. Sci. 58[1]:11–26) found that only 0.4% of non-invertebrate matter in *B. fowleri* stomach contents was animal in origin, 0% of which was amphibian.

Here we report an unusual case of conspecific scavenging in *Bufo fowleri*. On 3 July 2008 at 2315 h on Provincelands Road (42.05058°N, 70.22184°W; NAD 83) in Provincetown, Massachusetts, USA, we observed a terrestrial subadult *B. fowleri* (ca. 50 mm snout–urostyle length [SUL]) consuming a flattened, dried, road-killed conspecific (Fig. 1). The remains of the road-killed toad measured ca. 57 mm SUL. Because the road-killed individual broke as we removed it from the mouth of the live toad, we estimated the carcass to be a few millimeters longer than we report here, making the specimen slightly larger than the scavenging toad. We observed two live ants (Formicidae), a known prey item for *B. fowleri* (Clarke 1974, *op. cit.*; Klimstra and Myers 1965, *op. cit.*), on the carcass after we removed it from the mouth of the live toad. The live toad may have inadvertently picked up the road-killed individual, along with the more commonly consumed ants. However, we are unsure if the ants were in or on the carcass and visible to the toad during consumption. Though non-invertebrate material of animal origin has been documented in stomach contents of non-larval *B. fowleri*, our observation represents what is likely the only documented case of conspecific scavenging, active, passive, or unintentional, in non-larval *B. fowleri*.

FIG. 1. Juvenile *Bufo fowleri* consuming a road-killed conspecific.

CRAUGASTOR RANOIDES (NCN). **PREDATION**. Although a variety of predators are likely to feed on *Craugastor ranoides*, there are no cases of predation documented. On 15 April 15 at 2130 h, we observed a spider of the species *Ancylometes bogotensis* (Ctenidae) eating a juvenile C. *ranoides* at the Quebrada Grande, Guanacaste National Park, Costa Rica (10.90111°N, 85.74138°W; WGS 84). Except for the head, the frog was completely consumed in ca. 3 h. To confirm our observation, photographs were taken. After the predation event, the spider was collected for identification. The spider was identified by Diana Silva-Davila and deposited at the California Academy of Sciences (CASENT 9025506). A digital photograph of the event was deposited at the Museo de Zoología, Universidad de Costa Rica.

We thank Enrique González for taking the pictures and Mark Budworth for comments on this note.

CYCLORAMPHUS FULIGINOSUS (Tschudi's Button Frog). **SAUROPHAGY.** *Cycloramphus fuliginosus* is a poorly known frog associated with streams of the Atlantic coastal forest from Rio de Janeiro to southeastern Bahia, Brazil (Heyer 1983. Arq. Zool., S. Paulo 30:235–339; Heyer 1988. Proc. Biol. Soc. Washington 10:151–154; Verdade 2005. Unpubl. PhD thesis, Universidade de São Paulo, São Paulo, Brazil). In general, natural history data for *Cycloramphus* species are scarce and anecdotal. Little is known of their reproduction and defensive behavior, and there are virtually no data on the diet of these frogs. In turn, *Ecpleopus gaudichaudii* is a rare forest-litter dweller lizard, endemic to the Atlantic Forest of southeastern Brazil (Uzzel 1969. Postilla 135: 1–23). This lizard is difficult to observe and remains poorly known, with only the description, and a single note on its diet available in literature (Eisemberg et al. 2003. Herpetol. Rev. 35:336–337). Herein, we make the first report of saurophagy for the frog genus *Cycloramphus*.

While dissecting a specimen of *Cycloramphus fuliginosus* (52 mm SVL), we found a partially digested *Ecpleopus gaudichaudii* (30 mm SVL). The specimen was collected on 24 May 1952 at Tijuca, Rio de Janeiro municipality (22.94°S, 43.24°W), Rio de Janeiro state, Brazil. *Cycloramphus fuliginosus* is a large territorial frog, with all life stages strictly associated with streams (Lutz 1929. Mem. Inst. Oswaldo Cruz 22:5–25; Heyer 1983, *op. cit.*; Izecksohn and Carvalho-e-Silva 2001. Anfíbios do Município do Rio de Janeiro, Editora UFRJ, Rio de Janeiro), whereas *E. gau-*

dichaudii is an active forest litter forager (Eisemberg et al. 2003, *op. cit.*). This observation suggests *C. fuliginosus* is a generalist predator, as are most large species of frogs (Duellman and Trueb 1994. Biology of Amphibians. Johns Hopkins University Press, Baltimore, Maryland. 670 pp.). The frog and its prey are deposited at the herpetological collection of the Museu de Zoologia da Universidade de São Paulo, São Paulo, Brazil (MZUSP 9836).

DENDROBATES AURATUS (Green and Black Dart-poison Frog). **DIEL ACTIVITY.** Variation of diel activity of *Dendrobates auratus* has been studied in Panama (Dunn 1941. Copeia 1941:88–93) and Cost Rica (Graves 1999. J. Herpetol. 33:375–381), however no such studies exist for the introduced population on O'ahu, Hawai'i. We examined activity patterns in adults and compared this with temperature, time, and humidity in the field to identify the primary determinant of activity.

We examined activity patterns of adult *D. auratus* on the leeward side of the island of O'ahu, Hawai'i at and around the Harold B. Lyon Arboretum (21.33166°N, 157.8°W; WGS 84; 137–164 m elev.) during summer 2005. Three plots were established via natural and unnatural barriers. The first plot, the "arboretum" was ca. 0.375 km^2. Terrain consisted of paved area, mowed lawn, greenhouse structures, living quarters, and gardens. Vegetation included bromeliads (Bromeliaceae), pothos (*Scindapsus*), bird-of-paradise (Strelitziaceae), and *Heliconia* sp. (Heliconiaceae). The second plot, the "park" shared a paved border with the "arboretum" on the east and a stream border to the west. Total area was ca 0.125 km^2. Terrain consisted of undeveloped secondary forest, unmaintained paved area, and small (uninhabited) buildings. Vegetation consisted primarily of bamboo (Bambusoideae) and pothos, coconut (Arecaceae), and *Heliconia*. The third plot, the "farm" shared a border to the west with the "park" that consisted of a small (ca. 3 m across) stream. Total area was ca. 0.25 km^2. Terrain consisted of existing (but not frequented) dirt trails through secondary forest and uninhabited living quarters. Vegetation consisted of bamboo, pothos, and *Heliconia*.

Each plot was hiked and visually examined on random days by two observers for the duration of the experiment. Number of frogs observed was noted, as was time of day, temperature, and weather conditions. These observations were considered an indication of activity level as behaviors consisted of active foraging and courting.

Average daily rain data were collected from a rain gauge located on the Harold B. Lyon Arboretum grounds, owned by the National Weather Service Forecast Office (http://www.prh.noaa.gov/hnl/pages/hydrology.php).

The number of *D. auratus* observed ranged from 0 to 14 during an hour session. Activity gradually increased starting at sunrise and peaked at 3 h past sunrise, decreasing again in midday and increasing again in the early evening. Temperatures at which *D. auratus* were observed ranged between 23.5ºC and 30ºC (mean 26.13ºC ± 1.51ºC). Time and temperature did not appear correlated (R^2 = 0.146652), nor did daily rain totals and frogs observed (R^2 = 0.0057). To determine whether or not there was a correlation between plot and number of observed frogs, an ANOVA was performed and found not to be significant (df = 2, Q = 0.2240).

Our field study occurred throughout the breeding season, during which activity is at its highest (pers. obs). Dunn (1941, *op. cit.*) observed highest activity in the mornings and after rains in Panama. Graves (1999, *op. cit.*) observed highest activity midday. Our observations did not show a correlation between weather and activity but showed that time and activity correlated when examined as a bimodal function. Our time and temperature did not appear correlated. This is likely due to our temperature collection methods. Temperature was collected at the exact location where the frog was first detected using an electronic thermometer and thus, represents a highly variable microclimate reading which we would not expect to follow the parabolic relationship that intradaily air temperatures typically follow. Our observations suggest that the primary contributor to activity in *D. auratus* is temperature in its introduced habitat on the island of O'ahu, Hawaii.

ELEUTHERODACTYLUS ALTAMAZONICUS (NCN). **REPRODUCTION**. *Eleutherodactylus* species undergo direct development, forgoing an aquatic larval stage. It is generally assumed that species deposit eggs in trees within cavities or bromeliads, or on the ground amid moisture-retaining leaf litter or under rotting logs. However, records of oviposition by most species of *Eleutherodactylus* are rare.

On 26 May 2005, at 0830 h we encountered a male (22.3 mm SVL, 0.66 g) and female (34.5 mm SVL, 2.03 g) *Eleutherodactylus altamazonicus* in amplexus at the base of a large tree in primary, terra firme forest within Yasuní National Park in Ecuador (Provincia de Orellana). The pair was positioned over a small depression in the ground. The cavity was circular in shape, devoid of leaf litter, and roughly 3 cm in diameter and 1 cm deep. The pair was captured, placed together in a plastic bag and taken to the laboratory so measurements could be taken. Overnight, the female deposited 38 unpigmented eggs ca. 3.5 mm in diameter inside the bag. The eggs were returned to the depression from which the frogs were originally taken the next day. The study period ended 4 days after the pair was found, therefore we were unable to observe whether the eggs hatched. On 27 May, we encountered a second gravid *E. altamazonicus* female (32.1 mm SVL, 2.78 g) less than 100 m from the spot the first two individuals were encountered. These findings support suggestions that the beginning of the rainy season marks the onset of breeding in this species (Duellman 1978. Misc. Publ. Univ. Kansas, Mus. Nat. Hist. 65:1–352).

To our knowledge, only three other clutches have been described for *E. altamazonicus*. The clutch size reported here is much greater and the eggs larger than those clutches (mean number of eggs in other clutches = 18.7, mean size = 2.8 mm) (Duellman 1978, *op. cit.*). This difference may be attributable to the large size of the female or geographic variation in reproduction in this species.

I thank the staff at Yasuni Research Station for logistical sup-

port and Amo Enomenga for field assistance. This observation was made during dissertation research supported by grants from the Conservation, Food, and Health Foundation and the Louisiana Governor's Office of Environmental Education.

ELEUTHERODACTYLUS ATKINSI (NCN). **DIURNAL RETREATS.** *Eleutherodactylus atkinsi* is endemic to Cuba. It is widely distributed throughout Cuba, Isla de la Juventud, and some keys of the Sabana-Camagüey archipelago (Estrada and Ruibal 1999. *In* Crother (ed.), Caribbean Amphibians and Reptiles). It inhabits scrub, mesic woods, and forests as well as coffee, cacao, and banana plantations and the edges of cornfields. During the day it occupies refuges in small caves, pastures, under trash and fallen palm thatch; it is often found near human habitations (Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies: Descriptions, Distributions, and Natural History. Florida Univ. Press, Gainesville, 720 pp.). In this note we report an opportunistic and unusual retreat of this Cuban endemic frog.

During the morning of 25 Jan 2007, we found a great density of sticky mounds (ca. 90 m^2) (Fig.1A) near a shallow stream in a heavily altered area of secondary vegetation in Baitiquirí, Guantánamo province (20.03090°N, 74.8704°W; NAD 27 for Cuba). The mounds had a central burrow dug as shelter by a fiddler crab, *Uca* sp. (Ocypodidae). During the night (ca 2030 h) we observed male, female (including gravid individuals), and juvenile *E. atkinsi* emerge from the crab burrows to vocalize and forage (Fig. 1B).

During two consecutive nights (between 2000–2200 h) we observed the frogs' behavior. On the second night, we counted the number of frogs observed in each mound and characterized the crab burrows by measuring the following: height of the mound (HB), diameter of the opening (DB), temperature near to the opening (TB), soil humidity (Dry/Moist), and aperture condition (Open/Close). Below we present the mean and standard deviation (mean ± SD) of each mound characteristic measured and the mode of the number of frogs in each mound.

We inspected 64 crab burrows and found frogs in 48. The number of frogs in each mound (1.22 ± 0.87) ranged from 0–4 (mode = 1, N = 37 burrows, 57.8%). The crab burrows used by *E. atkinsi* had DB = 40.2 ± 14.2 mm, average HB = 10.8 ± 4.8 mm; temperature near the opening varied less than 1ºC among burrows (22.8 ± 0.81ºC).

Some species of frogs have been observed using the shelters of spiders and crabs as a regular daytime retreat, apparently coexisting with the original inhabitants (Cocroft and Hambler 1989. Biotropica 21:2–8; Dundee 1999. Herpetol. Rev. 30:91–92; McIntrye 2003. Herpetol. Rev. 34:52–53). We noted the presence of active crabs in the area, new burrow construction between nights, tracks, and other evidence suggesting coexistence between frogs and crabs. Our observations of the opening/humidity conditions of the burrows on the second night indicate that the frogs occurred in higher frequency in dry conditions (37 of 41 dry burrows had frogs), independent of opening condition. This suggests that frogs preferred mounds not recently disturbed by crabs. The only report

FIG. 1. A. Density of crab burrows at study site in Baitiquirí, Guantánamo Province (the white arrow indicates the mound shown in (B). B. Mound with four *Eleutherodactylus atkinsi* (white circles) emerging from their diurnal retreat.

of crabs preying on frogs in Cuba is that of Fong and Hero (2005. Tech. Rept., DAPTF) who reported the freshwater crab *Epilobocera cubensis* preying on an adult *Eleutherodactylus cuneatus* in La Gran Piedra, Eastern Cuba.

Some species of anurans are opportunistic burrowers and often use natural holes, crevices, or tunnels made by other animals (Wells 2007. The Ecology and Behavior of Amphibians. Univ. of Chicago Press, Chicago, Illinois). The use of these pre-existing burrows as diurnal refuge provide more stable conditions of temperature and humidity than do more exposed locations, and also provide protection from desiccation and diurnal predators (Wells 2007, *op. cit*). To our knowledge this is the first report of the opportunistic use of pre-existing burrows by *E. atkinsi* and the second for Cuban amphibians. An individual *Peltophryne peltacephala* was observed using the nest of a Burrowing Owl (*Speotyto cunicularia*) as a diurnal retreat (Valdés de la Osa 1978. Misc. Zool. Acad. Cien. Cuba. 7:4).

We thank A. Daniel and I. Ramos for assistance during field work. Ricardo Estevez and other local people provided hospitality and help. Gerardo Begué and the authorities of the National System of Protected Areas in Guantánamo province facilitated access to the study area. Ariel Rodriguez made comments on the manuscript. The Cuban project "Colecciones Zoológicas: Conservación y manejo" of the Institute of Ecology and Systematics, Havana, Cuba, helped fund fieldwork.

ELEUTHERODACTYLUS DIMIDIATUS (NCN) **AND *ELEUTHERODACTYLUS INTERMEDIUS*** (NCN). **PREDATOR/PREY**. On 18 Sept 2005 (ca. 2300 h) we witnessed an adult *Eleutherodactylus dimidiatus* (26.1 mm SVL) eating an adult *E. intermedius* (18.6 mm SVL). The frogs were observed among leaf litter in secondary vegetation in montane rainforest at La Gran Piedra (20.0°N, 75.61666°W; WGS 84; elev. 1100 m), Santiago de Cuba Province, Cuba.

FIG. 1. Adult *Eleutherodactylus dimidiatus* eating an adult *E. intermedius*, La Gran Piedra, Santiago de Cuba, Cuba. Photograph by R. Alonso.

When first observed, the *E. dimidiatus* was grasping the hind legs of the *E. intermedius*, with the head and the front legs of the prey emerging from its mouth (Fig. 1). We observed the frogs' interaction with headlamps and took pictures using flashes for ca 10 min. We then removed the leaf litter around the frogs, but the predator never changed its behavior and only moved a few centimeters from its initial position.

Our observation represents the first record of a predator/prey relationship between wild *Eleutherodactylus* frogs in Cuba, although Valdés de la Osa and Ruiz-García (1977. Misc. Zool. 6:4) reported cannibalism in captive *E. riparius* (identified as *E. cuneatus*). Specimens were deposited in the herpetological collection of BIOECO, Santiago de Cuba (Field number AFG 2946).

We thank Jaime Bosch and Ana Beatriz Díaz-Guerra for help with field work.

Romay," Enramadas #601, Santiago de Cuba 90100, Cuba (e-mail: ansel@bioeco.ciges.inf.cu); **ROBERTO ALONSO** (e-mail: ralonso@ecologia.cu) and **ARIEL RODRÍGUEZ** (e-mail: ariel@ecologia.cu), División de Colecciones Zoológicas y Sistemática, Instituto de Ecología y Sistemática, Carretera de Varona Km 3½, Capdevila, Boyeros, AP 8029, CP 10800, Ciudad de la Habana, Cuba.

ELEUTHERODACTYLUS LEBERI (NCN). **CLUTCH SIZE AND PARENTAL CARE.** *Eleutherodactylus leberi* is an endemic Cuban frog of the subgenus *Eleutherodactylus* (Hedges 1989. *In* Woods (ed.), Biogeography of the West Indies: Past, Present and Future, pp. 305–370. Sandhill Crane Press, Gainesville, Florida). The species is restricted to the northern slope of the Sierra Maestra in eastern Cuba (Estrada and Ruibal 1999. *In* Crother (ed.), Caribbean Amphibians and Reptiles, pp. 31–62. Academic Press, San Diego, California). During a herpetological expedition to the Sierra Maestra in June 2003, several calling male *E. leberi* were collected among the rocks and vegetation surrounding La Tabla (20.204194°N, 76.39588°W; NAD 27 Cuba datum). Voucher specimens were verified by L. V. Moreno and were deposited in the Instituto de Ecología y Sistemática, Colección Zoológica de la Academia de Ciencias de Cuba (CZACC 14.11530–36). One of the calling males was vocalizing at 2055 h from a small cavity in the rocky wall of "diente de perro," the karstic landscape typical of this region, and was observed in close contact with a clutch of eggs. This individual remained close to the clutch when disturbed by our headlamps, and escaped only when we attempted to photograph the cavity. The clutch of 27 spherical eggs (one measured 5.8 mm diameter) was at the end of the cavity (1.8 cm diameter, 6.4 cm deep). The eggs were contained in a jelly cluster adhered to a rock; seven were dark and seemed infertile, the rest were creamy-white. Air temperature measured inside the cavity was 23.3ºC; outside was 22.6ºC. To the best of our knowledge these are the first data regarding clutch size of *E. leberi*, a feature that is largely unknown for most of the Cuban *Eleutherodactylus*. Additionally, the behavior of this male provides the first evidence of parental care in this species in the form of egg attendance, a behavior reported in other Cuban *Eleutherodactylus*: *E. albipes*, *E. atkinsi*, *E. dimidiatus*, *E. guantanamera*, *E. intermedius*, *E. tetajulia,* and *E. varleyi* (Wells 2007. The Ecology and Behavior of Amphibians. University of Chicago Press, Chicago, Illinois. 1148 pp.).

HYLA CINEREA (Green Tree Frog) and ***PSEUDACRIS TRISERIATA*** (Western Chorus Frog). **CALLING IN AMPLEXUS**. Anurans are known for their large breeding choruses in which males gather to attract mates. Females approach these choruses and phonotactically evaluate and respond to males whose voice qualities are believed to communicate fitness (Ryan 1985. The Tungara Frog: A Study in Sexual Selection and Communication. Univ. Chicago Press, Chicago, Illinois). Because females enter the choruses over the entire breeding chorus, rather than simultaneously, competition between males is severe. Consequently, males that amplex the first available female "choosing" them should be at a selective advantage to males that reject less favorable females.

On 23 Feb 2000 at ca. 2130 h in Craighead County, Arkansas, USA (T13N, R2E, Sec. 12), ca. 2.4 km S of U.S. Hwy 49 on CR 204, we observed a chorus of *Pseudacris triseriata*. Several specimens were collected and returned to the Arkansas State University Herpetology Museum for examination. Upon return to the museum, two of the frogs had paired in amplexus. This pair was isolated to collect the eggs. At 0130 hr in amplexus, the male began calling. The male continued calling sporadically for about one hour. Eggs were recovered the next morning, but none hatched.

On 29 May 2000 at ca. 2030 h a chorus of *Hyla cinerea* was visited in a rice field in Craighead County, Arkansas, USA (T13N, R4E, Sec. 31) at the junction of CR 452 and Arkansas Highway 1, ca. 11.2 km S of Jonesboro. While collecting calling males, one male was found calling while in amplexus with a female. The pair was captured, and they quickly separated. Both frogs were deposited in a 1-liter plastic bag with five other males. After

returning from the field at 0200 h, a male was observed amplexed with the female again. It is unknown whether this was the same male as before, but there was only one female in the bag. The pair was removed and placed in their own bag to recover the eggs. At ca. 0215 h the male in amplexus began calling and continued for at least 15 minutes. He then ceased and did not call again before 0245 h when observations ceased. In the morning, a clutch of eggs was present, and the frogs were no longer in amplexus. The calls were typical breeding calls and bore no resemblance to aggression or release calls observed in both species.

Apparently, there are no previous reports of males producing breeding calls while in amplexus, but this is a very significant adaptation for a male. Obviously, the implications of amplectant calling behavior are quite dramatic. Because the pairs observed were isolated, there is no way to know if the males would switch mates. Nevertheless, the selective advantage that could be incurred by participating in such an action cannot be ignored.

KALOPHRYNUS INTERLINEATUS (Striped Sticky Frog)**. DIET.** The information on amphibian diets suggests that all adult amphibians are carnivores; most feed principally on insects, although many species eat a wide variety of invertebrates (Duellman and Trueb. Biology of Amphibians 1986. McGraw-Hill Book Co., New York. 670 pp.). Here we report prey of *Kalophrynus interlineatus* from the Trat Agroforestry Research Station, Muang District, Trat Province, southeastern Thailand. A frog was caught at 2030 h on 23 Jan 2008 in dry, evergreen secondary forest (12.40129°N, 102.67195°E; WGS 84; 20 m elev.). It was kept overnight in a plastic bag. Later the next morning, we collected a fecal pellet (field no. Y 0373) from the bag and the frog was released into its natural habitat.

The pellet was dominated by ants (Formicidae), which comprised 13 of 14 identifiable prey items. These included eight *Camponotus* sp., two *Odontomachus* sp., one *Pheidole* sp., one *Pheidologeton affinis*, one *Polyrhachis* sp., and one unidentified beetle belonging to the family Scarabaeidae. This information provides preliminary data on the diet of *K. interlineatus* in Thailand.

Submitted by **YODCHAIY CHUAYNKERN**, Muséum National d'Histoire Naturelle, Département de Systématique et Evolution, Reptiles et Amphibiens, 25 rue Cuvier, F-75005 Paris, France and Thailand Natural History Museum, Technopolis, Khlong 5, Khlong Luang, Pathum Thani, 12120 Thailand (e-mail: ychuaynkern@yahoo.com); **AMORNRAT WONGWAI** (e-mail: morn19919@hotmail.com), **PRATEEP DUENGKAE** (e-mail: prateep@ku.ac.th), and **SASITRON HASIN** (e-mail: Lucifer_pae62@yahoo.com), Department of Forest Biology, Faculty of Forestry, Kasetsart University, Jatujak, Bangkok, 10900 Thailand.

KALOPHRYNUS INTERLINEATUS (Striped Sticky Frog)**. ANTIPREDATOR BEHAVIOR.** Here we report antipredator behavior of *Kalophrynus interlineatus* from southeastern Thailand. The frog was caught at 2030 h on 23 Jan 2008 in dry, evergreen secondary forest (12.40129°N, 102.67195°E; WGS 84; 20 m elev.), Trat Agroforestry Research Station (Muang District, Trat Province). It was kept overnight in a plastic bag. When touched near the vent the following morning (similar to Chuaynkern et al. 2007. Herpetol. Rev. 38:321–322), the individual inflated its lungs and elevated the body, especially the pelvic region, thereby presenting the ocelli-like marks on the pelvic region (Fig. 1). A somewhat similar defensive posture—lowering the head and elevating inguinal glands—is shown by *Physalaemus nattereri* (Duellman and Trueb 1986. Biology of Amphibians. McGraw-Hill Book Co., New York. 670 pp.), However, we did not observe lowering of the head in *K. interlineatus*. Presentation of the ocelli-like marking on the pelvic region has been interpreted as "eyespots" with the suggestion that the broad pelvic region with elevated "eyes" gives the image of a much larger organism (Duellman and Trueb 1986, *op. cit.*). Chan-ard 2003. (A Photographic Guide to Amphibians in Thailand. Darnsutha Press Co., Ltd., Bangkok. 175 pp.) suggested *Kalophrynus* used ocelli-like markings to present an image of a snake with open mouth.

FIG. 1. Defensive posture by *Kalophrynus interlineatus*, inflating of lungs and elevating of body. Photograph by Prateep Duengkae.

LIMNONECTES MEGASTOMIAS (Big-mouthed Frog). **DIET and ORNITHOPHAGY**. The recently described frog, *Limnonectes megastomias*, is currently known from only two localities in northeastern Thailand (McLeod 2008. Zootaxa 1807:26–46).

On 27 June 2003, a series of *L. megastomias* was collected from the type locality, a dry evergreen forest at Sakaerat Environmental Research Station, Nakhon Ratchasima Province, Wang Nam Khieo District, Thailand (14.49°N, 101.87°E; Indian-Thailand Datum; 645 m). During collecting, an adult male *L. megastomias* was found to have recently ingested an adult male *L. gyldenstolpei*, the only other anuran known to co-occur with *L. megastomias* at this site. On 15 March 2005, another series of 13 specimens (11 males, 2 females) was collected at the same locality and maintained in captivity until 17 March 2005. Feces from these frogs, containing feathers and other prey items, were preserved as a dietary voucher. Feathers were identified as those of a Leaf Bird, *Chloropsis* sp. Invertebrate remains were identified as belonging to species of Coleoptera (Carabidae; Scarabidae, 2 spp.; 1 undetermined taxon), Hemiptera (2 undetermined taxa), Hymenoptera (Meliponinae; Formicidae), Isoptera (Termitidae), and Lepidoptera (2 undetermined taxa).

Based on personal observations, *L. megastomias* seems to be a sit-and-wait predator, often found partially submerged in water at the edge of a waterway with only eyes and snout exposed. Occasionally, individuals are seen on the stream bank. These frogs, males in particular, have a relatively large gape, and it is conceivable that a bird landing on the bank of the stream might be consumed in the same opportunistic manner that a conspecific *L. gyldenstolpei* would be.

There are infrequent examples in the literature of anurans preying on birds (Duellman and Trueb 1994. Biology of Amphibians. The John Hopkins University Press, Baltimore, Maryland. 670 pp.). This represents the only account that I am aware of documenting an Asian anuran preying on birds.

I thank T. Artchawakom (SERS), P. Panyawattanaporn, and W. Kongtong (National Research Council of Thailand), and K. Thirakhupt and W. Khonsue (Chulalongkorn University) who facilitated this work in 2003 and 2005; K. Hesed for his assistance in the field. D. Karns, H. Voris, and J. Murphy were responsible for my 2002 visit to SERS. Mark Robbins and Z. Falin identified the bird and insect remains. Funding was provided by grants from the USGS, The David L. Boren graduate fellowship, The University of Kansas Department of Ecology and Evolutionary Biology, and the Natural History Museum and Biodiversity Research Center. Linda Trueb provided valuable comments on this note.

LITHOBATES CATESBEIANUS (American Bullfrog)**. PREDATION ON CLIFF SWALLOWS.** The American Bullfrog is known to have a broad, omnivorous diet that includes plant material, aquatic and terrestrial invertebrates, and vertebrates (Bury and Whelan 1986. Ecology and Management of the Bullfrog. USFWS Res. Publ. 155. Washington, DC). During a 25-year study of Cliff Swallows (*Petrochelidon pyrrhonota*) in southwestern Nebraska, we observed *Lithobates catesbeianus* prey on, or attempt to prey on Cliff Swallows. Cliff Swallows feed exclusively on insects caught in flight. They are quick, agile fliers and rarely alight on the ground (Brown and Brown 1996. Coloniality in the Cliff Swallow: The Effect of Group Size on Social Behavior. University of Chicago Press, Chicago, Illinois), thus they are very unlikely prey for *L. catesbeianus*.

As we were mist-netting Cliff Swallows at a 10-nest colony on 7 July 1998, a *L. catesbeianus* attempted to eat a Cliff Swallow that was caught in the net. We were dropping the net over the side of a road culvert (Brown and Brown 1996, *op. cit.*; Lueschen 1962 Eastern Bird-Banding Association News 25:109) in which the birds' nests were built, near Roscoe, Keith County, Nebraska, USA (41.11931°N, 101.57523°W; NAD 83). When the net was lowered into place, the top was ca. 45–60 cm above the ground. The birds were caught in the net when they flew out of the culvert. The net was lowered over the culvert entrance for, at most, 10 seconds. A wet, marshy area, with ca. 20–25 cm of standing water, was situated at the mouth of the culvert. On one drop, with 3 adult swallows in the mist-net, a large (36–41 cm SVL) *L. catesbeianus* jumped up into the net from the standing water and caught a swallow by the head. We immediately raised the net. In the 15–20 seconds it took to raise and secure the net, the frog had swallowed the bird as far down as the bird's legs. The bird was still alive although seemingly stunned, and its feathers were matted with saliva when removed from the frog's mouth. The *L. catesbeianus* was released unharmed.

OSTEOPILUS SEPTENTRIONALIS (Cuban Treefrog). **PREY.** The Cuban Treefrog is a large (to 165 mm SVL; Meshaka 1996. Herpetol. Rev. 27:74), predominantly nocturnal frog native to Cuba, the Isla de Pinos, the Cayman Islands, and the Bahamian Archipelago (Duellman and Crombie 1970. Cat. Amer. Amphib. Rept. 92:1–4). It commonly preys on invertebrates but has been observed feeding on small vertebrates including conspecifics (Peters 1974. Mitt. Zool. Mus. Berlin 50:299–322), small snakes, and hatchling birds (Bartlett and Bartlett 1996. Frogs, Toads, and Treefrogs. Barrons Publ., Hauppauge, New York). Here I report a diurnal predation attempt on an adult bird.

While working as a guide at Tiamo Resorts, a lodge on South Andros Island in the Bahamas in April 2006, I witnessed an adult Bananaquit (*Coereba flaveola*) ca. 110 mm long alight on a wooden handrail within 50 mm of a sleeping *O. septentrionalis* of comparable size; the frog awoke and attempted to catch the bird, succeeding only in grasping its retrices (tail feathers), which were shed in the ensuing struggle after which the bird escaped. The frog then retreated and closed its eyes with the feathers still protruding from its mouth. After ca. 3 min., still with eyes closed, the frog proceeded to push the feathers into its mouth with its forelimbs and consume them. This is the first recorded predation attempt by a Cuban Treefrog on an adult avian. I thank Bob Powell and Bob Henderson for providing comments on this note.

OSTEOPILUS SEPTENTRIONALIS (Cuban Treefrog). **REPRODUCTION.** *Osteopilus septentrionalis* is native to Cuba, the Cayman Islands, and the Bahamas, including the Exumas, but has been extensively introduced or accidentally released outside its native range (Schwartz and Henderson 1988. Milw. Publ. Mus. Contrib. Biol. Geol. 74:1–264). However, its need for standing freshwater to reproduce has likely limited the ability of Cuban Treefrogs to colonize and successfully reproduce on small cays in the Bahamas because standing freshwater is often at a premium on these islands. Herein we report successful reproduction of *O. septentrionalis* on Southwest Allen's Cay (U Cay) in the Exumas in the central Bahamas (24.75°N, 76.84166°W; WGS 84; see Iverson et al. 2004. Herpetol. Monogr. 18:1–36 for a detailed description).

The presence of adult *O. septentrionalis* was first detected on U Cay in May 2001 (GRS and JBI, pers. obs.). Standing freshwater on U Cay is very limited, and frequently non-existent, except for short-term rain puddles. However, the presence of jetsam has created more permanent freshwater habitats on this island, and indeed the first adult *O. septentrionalis* was associated with an upright freezer found in the interior of the island (GRS and JBI, pers. obs.). We report on our observation of successful production of metamorphs from this upright freezer-based freshwater habitat. Metamorphs were observed on 14 May 2008, as well as numerous tadpoles ranging across several developmental stages and sizes. Our observation suggests that human-derived habitats may allow *O. septentrionalis*, and other amphibians, to colonize previously uncolonized islands and cays. Indeed, in Florida *O. septentrionalis* has been extremely successful at exploiting human-associated habitats, including reproducing in a variety of human-created habitats (e.g., cisterns, birdbaths, etc.; Meshaka 2001. The Cuban Treefrog in Florida: Life-history of a Successful Colonizing Species. University Press of Florida, Gainesville. 191 pp.), and its ability to colonize Anguilla appears to be tied to the use of cisterns (Townsend et al. 2000. Caribb. J. Sci. 36:326–328). The effect of such human-mediated colonization and reproduction on these small cays is not clear, and warrants further investigation.

Funding for this research was provided by Earlham College, the Cope Museum Fund, and the Test Fund. Permits were issued by Bahamas Department of Agriculture for iguana research to JBI.

PHYLLOMEDUSA CAMBA (NCN). **MAXIMUM SIZE.** *Phyllomedusa camba* is distributed throughout the southwestern Amazon of South America from southeastern Peru and western Brazil to eastern Bolivia (De la Riva 1999. Rev. Esp. Herpetol. 13:123–31). Previous studies have reported the maximum snout–vent length (SVL) of the species to be 84.0 mm for females and 73.3 mm for males; the maximum mass record for the largest female is 22.5 g and 18.5 g for the largest male (De la Riva 1999, *op. cit.*; De la Riva et al. 1995. J. Herpetol. 29:113–18; Duellman 2005. Cusco Amazónico. Cornell University Press, New York, pp. 253–254; Duellman and Thomas 1996. Univ. Kansas Nat. Hist. Mus. Occ. Pap. No. 180:1–34). Here we report a new size record for the species.

Reserva Amazónica, previously known as Cuzco Amazónico (ca. 12.541666°S; 69.052777°W, WGS 84; 195 m elev.) is located in Provincia Tambopata, ca. 12 km E Puerto Maldonado on the north shore of the Rio Madre de Dios in southeastern Peru. On 27 Dec 2007 (2300 h), an adult *Phyllomedusa camba* was observed on a branch ca. 1 m above the ground. The branch extended over Trail-A ca. 200 m from the beginning of the trail. Although the frog was not collected, photographs and measurements were taken in the field at the time of capture and deposited at the University of Texas at Arlington (UTADC 1924–26). Measurements were taken with digital calipers and Pesola scales. Although we did not determine the sex of the frog, its large size (87.3 mm SVL; 42.5 g) suggests it was a female. Our record is the first for Reserva Amazónica since January and February 1990, when eight specimens (SVL range 68.9–73.9 mm; mass range 15.0–22.5 g) of this frog were found (Duellman 2005, *op. cit.*).

We thank I. De la Riva for reviewing this manuscript, J. A. Campbell for cataloguing the photograph, and Jose Koechlin and Inkaterra for logistical support.

JADIN**, Amphibian and Reptile Diversity Research Center and Department of Biology, University Texas at Arlington, Arlington, Texas 76019, USA.

POLYPEDATES LEUCOMYSTAX (Java Whipping Frog). **PREDATION.** Although invertebrate predators are known to feed on larval and metamorph anurans, predation of adult anurans by invertebrates are rarer, although regularly reported (see McCormick and Polis 1982. Biol. Rev. 57:29–58 for review). Here we report the first observation of predation upon an adult male *Polypedates leucomystax* by the Giant Water Bug, *Lethocerus deyrollei*, a commonly encountered belostomatid in Southeast Asia. The observation was made during the evening of 19 July 2006 in a buffalo pond in Sopchoun, Luang Prabang Province, Laos (19.7°N, 102.5333°E; WGS 84), a small village close to the Nam Kham River, a tributary of the Mekong River. *Polypedates leucomystax* is arboreal and builds foam nests on branches overhanging water. However, some populations lay eggs in a foam nest on the ground near the pond edge. This is the case of this population where the predated frog was disturbed by us and dove into the water. Predation on this species by the Giant Water Bug should be exceptional as these frogs have no aquatic phase. We caught the frog and water bug as soon as the observation was made, and the frog was already badly injured. Both specimens were deposited in the Muséum National d'Histoire Naturelle, Paris under the collection numbers MNHN 2006.3401 (*Polypedates leucomystax*) and MNHN 2006.3402 (*Lethocerus deyrollei*).

We thank Annemarie Ohler for the time shared in the field with one of us (SG).

POLYPEDATES LEUCOMYSTAX (Common Tree Frog). **SAUROPHAGY**. On 27 June 2006 at 2104 h, in the Philippines (island: Luzon, province: Cagayan, municipality: Gattaran, barangay: Nassiping; 17.97001°N, 121.65598°E, WGS84), I collected an adult female *Polypedates leucomystax* in the process of consuming an adult male *Cosymbotus platyurus* (Sauria: Gekkonidae). The encounter occurred after ca. 2 h of heavy afternoon rain at the Nassiping Reforestation Project (NRP), an area of ca. 200 ha consisting of natural secondary growth, agricultural areas, and artificial forest with introduced species (e.g., *Eucalyptus* sp.). Both the frog and the lizard were collected and deposited at the University of Kansas Natural History Museum and Biodiversity Research Center (*P. leucomystax*: KU 307625; *C. platyurus*: KU 307448).

When I first observed the pair, the frog was on the ground with the gecko's hind legs and tail protruding from its mouth (Fig. 1) a few meters from an open-walled, thatch-roofed gazebo at the main compound of the NRP. Geckos were common on nearby buildings and active after nightfall; *C. platyurus* was predominant, with *Gehyra mutilata*, *Hemidactylus frenatus*, and *Gekko monarchus* also present.

The average to slightly larger-than-average size of both individuals (*P. leucomystax*: 72.1 mm SVL, 20.5 g; *C. platyurus*: 60.3 mm SVL, 6.1 g), as well as their commonness and tolerance for disturbed, anthropogenic habitat, suggest that adult *P. leucomystax* may be a frequent predator on *C. platyurus* and other small, common geckos. Large geckos (e.g., *G. monarchus*) are not likely to be preyed upon as adults, but neonates may be vulnerable. For these two individuals, prey/predator ratios of length and weight were 0.84 and 0.30.

Although large anurans (e.g., *Ceratophrys ornata*, *Discodeles guppyi*, *Pyxicephalus adspersus*, and *Rana catesbeiana*) are known to consume large prey items, predation by anurans on vertebrates is considered a general exception (Duellman and Trueb 1994. Biology of Amphibians. Johns Hopkins University Press, Baltimore, Maryland. 670 pp.) The diet of *P. leucomystax* in the Philippines has previously been reported to include solely invertebrates (Alcala and Brown 1998. Philippine Amphibians: An Illustrated Field Guide. Bookmark, Inc., Makati City, Philippines. 116 pp.). Saurophagy also has been reported for the large New World treefrog, *Osteopilus septentrionalis* (Campbell 2007. Herpetol. Rev. 38:440).

RANA AURORA (Northern Red-legged Frog). **EGG MASS DISTURBANCE**. The negative effects of exotic organisms on amphibians, usually via predation and/or competition, are well documented, both globally (Kats and Ferrer 2003. Divers. Distrib. 9:99–110) and in the Pacific Northwest (Adams 2000. Ecol. Appl. 10:559–568; Kiesecker and Blaustein 1997. Ecology 78:1752–1760; Kiesecker and Blaustein 1998. Conserv. Biol. 12:776–787). Nutria (*Myocastor coypus*), a South American species introduced to Oregon in the 1930s for fur-farming, is known to damage vegetation and physical habitat, which has diverse indirect ecological effects (Sheffels and Sytsma 2007. Report on Nutria Management and Research in the Pacific Northwest. Portland State University Center for Lakes and Reservoirs, Portland, Oregon. 49 pp.). However, its effects on Pacific Northwest amphibians are unaddressed. Hence, here we describe disturbance to and disappearance of *Rana aurora* egg masses attributable to the foraging of Nutria.

In January–March 2005, TRC conducted visual encounter surveys (Crump and Scott 1994. *In* Heyer et al. (eds.), Measuring and Monitoring Biological Diversity: Standard Methods for Amphibians, pp. 84–92. Smithsonian Press, Washington, DC) for amphibian egg masses in a seasonal pond in a palustrine wetland complex on the Willamette River floodplain ca. 16 km N of Portland, Oregon, USA (45.66°N, 122.86°W; WGS 84; elev 4 m). Black Cottonwood (*Populus trichocarpa*), Oregon Ash (*Fraxinus latifolia*), and invasive Reed Canary Grass (*Phalaris arundinacea*) dominate the site, which is managed by the Oregon Department of Fish and Wildlife (ODFW). As part of a larger study, each egg mass was assigned a unique mark and monitored weekly. Two *R. aurora* egg masses initially detected on 10 February were missing on 3 March, when TRC found a vegetation platform at their former location constructed of the Common Rush (*Juncus effusus*) to which the egg masses had been attached. The platform, which included the bamboo stakes and flagging used to mark these masses, was littered with Nutria scat. Nutria, Beaver (*Castor canadensis*), Muskrat (*Ondatra zibethicus*), and a suite of waterfowl species are all recorded from this site, but the only sign near or on the damaged vegetation was that of Nutria. Thorough search of the area failed

to reveal the missing masses. TRC had last observed these masses on 24 February; at that time, both were intact and in Gosner Stage 17 (Gosner 1960. Herpetologica 16:183–190). Twenty-five other marked masses detected on the same initial date (10 February) were in Stages 13–17 on 24 February. Of these masses, 13 were in the process of hatching on 3 March, and eight had not yet begun to hatch, but even the hatching masses had remained mostly intact. Nutria commonly build platforms of compacted vegetation for resting, feeding, and grooming (Burt and Grossenheider 1980. A Field Guide to the Mammals, 2nd ed. Houghton Mifflin, Boston, Massachusetts. 289 pp.). We do not know the ultimate fate of the disturbed egg masses, but based on the chronology of nearby *R. aurora* egg masses that TRC first observed on the same date at the same developmental stage, hatching and total disintegration by 3 March was unlikely. During the first half of embryonic development, *R. aurora* egg masses are typically denser than the water in which they are laid, and they sink if detached from their brace (MPH, unpubl. data). Klaus Richter (pers. comm.) has experimentally shown that mortality increases in *R. aurora* egg masses artificially relocated to greater depth. Moreover, simply mechanically disturbing amphibian egg masses has been shown to decrease embryonic survival (Licht 1971. Ecology 52:116–124.; Garwood et al. 2007. Northwest. Nat. 88:95–97). In this study, *R. aurora* egg masses occasionally became detached from attachment vegetation on their own, but typically only as they aged and neared hatching, when they typically float. Moreover, in the absence of high wind or other substantial disturbance, such detached egg masses generally remained near the original oviposition site. Hence, *M. coypus* foraging has the potential to affect *R. aurora* reproduction both directly by displacement of egg masses, and indirectly by altering the availability of braces for attachment of eggs.

A grant from the Oregon Watershed Enhancement Board helped support this fieldwork. TRC conducted the work under permit No. 040-05 from the ODFW. We thank S. Beilke, C. Corkran, and L. Roberts for assistance.

Submitted by **TIERRA R. CURRY**, Center for Biological Diversity, PO Box 11374, Portland, Oregon 97211, USA (e-mail: tierra.curry@gmail.com); and **MARC P. HAYES**, Washington Department of Fish and Wildlife, Habitat Program, 600 Capitol Way North, Olympia, Washington 98501, USA (e-mail: hayesmph@dfw.wa.gov).

RANA CAPITO (Gopher Frog). **BURROW COHABITATION.** Gopher Frogs seek refuge in the burrows of Gopher Tortoises (*Gopherus polyphemus*), crayfish, and several species of small mammals, as well as in stump holes (Jensen and Richter 2005. *In* Lannoo [ed.], Amphibian Declines: The Conservation Status of United States Species, pp. 536–538. Univ. California Press, Berkeley). Although Gopher Frogs are difficult to locate and observe in terrestrial habitats because they spend much of their lives underground, adults are not thought to share burrows with conspecifics (Jensen and Richter 2005, *op. cit.*; Wright and Wright 1949. Handbook of Frogs and Toads of the United States and Canada. Comstock Publishing Co., Ithaca, New York. 640 pp.). Here we report observations of at least two, and possibly three, adult Gopher Frogs occupying a Gopher Tortoise burrow simultaneously.

During a radio-telemetry study on Gopher Frogs conducted in the Ocala National Forest, Marion and Putnam counties, Florida, USA, we observed one transmitter-equipped adult Gopher Frog (Frog 1) sitting beside a large Gopher Tortoise burrow on 8 Oct 2007 at 2030 h. We also observed a second adult Gopher Frog (Frog 2), which was not equipped with a transmitter, sitting in the entrance to the same burrow (Fig. 1). Frog 1 had left a breeding pond within the previous 24 h, which was located 112 m from the burrow. Gopher Frogs can occasionally be observed sitting beside burrows at night and often create distinctive resting areas, consisting of soil cleared of vegetation (Richter et al. 2001. J. Herpetol. 35:316–321). Thus, although only one frog was actually inside the burrow, the two frogs probably shared the burrow diurnally.

FIG. 1. Two adult Gopher Frogs (*Rana capito*) observed at a Gopher Tortoise (*Gopherus polyphemus*) burrow in the Ocala National Forest, Florida. One frog (left) was in the burrow entrance, while the other frog (right) was sitting beside the burrow.

On 11 Oct at 2100 h, following a prescribed fire earlier that day, Frog 1 and a second transmitter-equipped adult Gopher Frog (Frog 3) were both located inside the same Gopher Tortoise burrow described above. Frog 1 had remained in the burrow since 8 Oct, and Frog 3 was located in leaf litter 22 m from the burrow during the previous day. Although no frogs were visible, Frog 2 may have also remained in the burrow since 8 Oct and thus may have been a third frog occupying the burrow. The two frogs with transmitters (Frogs 1 and 3) cohabited this burrow for 11 days until 22 Oct when Frog 3 moved 30 m into a stump hole.

Although adult Gopher Frogs have not been previously reported to cohabit burrows with conspecifics, they may only share them temporarily during fires or migrations to and from breeding ponds, or cohabitation may be more common than previously thought, but rarely observed due to the difficulty in monitoring individuals at burrows.

The Florida Fish and Wildlife Conservation Commission provided funding for the radio-telemetry study on Gopher Frogs.

RHINELLA JIMI (Cururu Toad) and ***LEPTODACTYLUS VASTUS*** (Northeastern Pepper Frog). **PREDATION ON BATS.** Anurans are primarily sit-and-wait foragers, and capture primarily insect prey (Toft 1981. J. Herpetol. 15:139–144). The predation of bats by two anuran species, *Rhinella jimi* and *Leptodactylus vastus*, was observed at the entrance of the Casa de Pedra cavern in Itabaiana, in the Brazilian state of Sergipe (10.833°S, 37.450°W; SAD 69). The cave is ca. 200 m long and has an internal temperature of ca. 39ºC. The entrance is ca. 5 m wide × 1.5 m high. The predation of a bat by *L. vastus* was first observed in 1998, and additional observations involving *L. vastus* and *R. jimi* were recorded in 2006 and 2008.

As night falls, individuals of both species position themselves close to the cave entrance to wait for the "explosive" (Fenton et al. 1994. Anim. Behav. 48:9–18) exit of the resident bats, which fly outside to forage between 1730 h and 2200 h. As they crowd through the narrow opening, some of the bats collide with each other and may fall to the ground, where the anurans are waiting. As soon as a bat falls to the ground, one of the anurans pounces rapidly forward to seize the animal directly in its mouth, without using its tongue (Fig. 1).

Although anurans are known to prey on many types of vertebrates (Duellman and Trueb 1986. Biology of Amphibians. McGraw-Hill, NewYork. 670 pp.), this appears to be the first record of feeding on bats, and might be related to specific circumstances. Analysis of stomach contents revealed the predation of Wagner's Mustached Bat (*Pteronotus personatus*) by both anurans. *Leptodactylus vastus* was also observed preying on a Mexican Funnel-eared Bat (*Natalus stramineus*). As records now span a decade, it is clear that a foraging "tradition" has been established in these anuran populations, although more observations are required to assess the importance of this behavior in ecological terms.

We thank Celso Morato de Carvalho for identification of the anurans, Renato Gomes Faria, João Pedro Souza Alves, Fábio Nascimento dos Santos, and Stephen Ferrari for revision of the text.

RHINELLA ORNATA (NCN). **PREDATION**. *Rhinella ornata* is a small bufonid found in the states of São Paulo, Rio de Janeiro, Espírito Santo, and Paraná, Brazil (Baldisscra et al. 2004. Nat. Mus. Rec. 62:255–282). In the region of Botucatu, SP, Brazil (22.8495°S, 48.4284°W; WGS 84), the species breeds in permanent ponds next to the forest during the dry season, between May and September. The males vocalize from the shallowest edges of the pond, but it is common to see them moving throughout the pond searching for females. In August 2005, a *Salminus brasiliensis* (Characidae) was captured in a pond in the Aquaculture Division of the School of Veterinary and Animal Science in the Paulista State University of Botucatu. This fish had a recently ingested *R. ornata* in its stomach. The anuran was a female with mature eggs in its ovary and was swallowed headfirst (Fig. 1). There are few reports of adult frogs being eaten by fish. The presence of toxic secretions on the skin and especially in the parotid glands, protects the toads from predators. The poison glands of *R. ornata* are not big and the quantity of poison stored can be very small or the poison toxicity can be very low, thus not affecting the fish (Cardoso and Sazima 1977. Cic. Cult. 29[10]:1130–1132).

We thank I. A. Martins for suggestions on the text, and CNPq for financial support (S. C. Almeida, proc. 141733/2006-3).

SCAPHIOPHRYNE CALCARATA (NCN). **TADPOLE BIOLOGY**. *Scaphiophryne* tadpoles are unique in their morphology as they are intermediate between the ranid and microhylid types. They possess neither keratinized teeth nor horny beaks, but are equipped with rows of oral papillae. This morphology allows them to filter-feed as well as to use their papillae as instruments to wipe particles off the substrate or to churn up particles from the bottom.

In the dry deciduous forest of Western Madagascar, *S. calcarata* tadpoles occasionally form aggregations where members may benefit from feeding as a group. On several occasions from 1999 to 2002 I observed dense aggregations of 20–100 tadpoles in small puddles (surface area 1–3 m^2, no tadpole predators present) within the Kirindy/CFPF Forest, a 10,000 ha remnant of the deciduous dry forest of Western Madagascar. In each of these aggregations, a few (5–10) tadpoles were digging with their mouthparts into the muddy substrate, ingesting it, and thereby churning it up. The majority of tadpoles in such an aggregation, however, were clumped behind these digging tadpoles, and were obviously filtering the stirred-up substrate. These tadpoles likely profit from the action of the others by increasing their ingestion rate without increasing their feeding costs. This observation supports the view that a feeding benefit, in addition to predation avoidance, is a factor leading to the formation of social aggregations in tadpoles.

SCAPHIOPUS HOLBROOKII HOLBROOKII (Eastern Spadefoot). **MAXIMUM SIZE.** The maximum body size reported for *Scaphiopus h. holbrookii* is 7.3 cm SVL (Conant and Collins 1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America, 3rd ed., expanded. Houghton Mifflin Co., Boston, Massachusetts. 616 pp.; Wasserman 1968. Cat. Am. Amphib. Rept. 70:1–4). Herein we report a record SVL for *S. h. holbrookii*.

A male *S. h. holbrookii* was captured in a box trap on 23 Oct 2007, following a 9.5 cm rain event the previous evening on the Camp Shelby Joint Forces Training Center, Perry Co., Mississippi, USA. The mean SVL of this individual was 7.8 cm (SE = 0.03, N = 5). The SVL was measured from the tip of the snout to the posterior edge of the vent with the anuran placed on its back. The mean SVL was determined from independent measurements by five herpetologists; this reduced possible biases in individual measuring techniques and provided a measure of dispersion (standard error) for SVL. All measurements were made to the nearest millimeter with either a standard metric ruler or digital calipers.

The *S. h. holbrookii* was deposited into the herpetological collection of the Mississippi Museum of Natural Sciences (MMNS 16000). We thank Matthew Hinderliter, Aaron Holbrook, and Thomas Radzio for their measurements.

Submitted by **JAMES R. LEE** (e-mail: jlee@tnc.org) and **CARMEN SABETTE**, The Nature Conservancy, Camp Shelby Joint Forces Training Center, CSJFTC-ENV Building 622, Camp Shelby, Mississippi 39407, USA.

SYRRHOPHUS NITIDUS (Shiny Peeping Frog). **DEATH FEIGNING**. Many anurans rely on escape behavior to avoid predation, but some, especially species incapable of rapid escape, have developed various defensive behavior in response to encounter by predators (Duellman and Trueb 1986. Biology of Amphibians. McGraw-Hill, New York. 670 pp.). Death feigning is a common anti-predator behavior in amphibians, and has been observed in several species of anurans (Fatorelli and Duarte 2005. Herpetol. Rev. 36:301; Kokubum 2005. Herpetol. Rev. 36:299). Herein, death feigning is reported in *Syrrhophus nitidus*, a species endemic to Mexico.

On 2 Aug 2006, along a creek in Quilamula, Morelos, México, a *S. nitidus* was observed on the ground. One of us (CAMS) lifted it gently with the hand to identify it. At the moment of opening the hand, the frog was found lying on its back with the eyes closed with one of the hind legs extended, feigning death. The frog kept that position for 40 sec., after which it turned quickly and tried to jump to the ground. A couple of days later the same behavior was observed in three more individuals. All of them displayed the death feigning behavior when lifted from the ground. Some of the frogs stayed still on the palm of the hand from 40 seconds to one minute. All were video-taped and released where found. We believe this to be the first published report of death feigning in *Syrrhophus nitidus*.

Submitted by **CARLOS AUGUSTO MADRID SOTELO** (e-mail: madridherp@aol.com) and **PAULINA CIFUENTES RUIZ,** Laboratorio de Biodiversidad, Dirección General de Divulgación de la Ciencia, Universum, UNAM, Zona Cultural Universitaria, CP 04510, México, D.F.

CROCODYLIA — CROCODILIANS

CROCODYLUS MORELETII (Morelet's Crocodile). **NESTING ECOLOGY.** Nesting season for *Crocodylus moreletii* begins with clutch deposition between May and mid-July, though laying maxima occur between mid-June and mid-July. Hatching occurs between August and October (Casas-Andreu and Rogel-Bahena 1986. An. Inst. Cienc. Mar Limnol., Univ. Nac. Auton. México. 13:323–330; Platt et al. 2008. J. Zool. 275:177–189). *Crocodylus moreletii* is regarded as a species that builds a mound nest, composed of vegetation, soil, leaves, and woody debris (Álvarez del Toro and Sigler 2001. Los Crocodylia de México. 1ª Edición, Imernar, Profepa, México. 134 pp.; Platt et al. 2008. J. Zool. 275:177–189). However, few data exist on nesting habitat and the material for nesting across the range of *C. moreletii*. Hence, here we present observations on its nesting ecology during 2007–2008

On 20 June 2007, we discovered a nest of *C. moreletii* at the precise moment of hatching in El Cuyo, Campeche, México (19.99806°N, 90.46528°W, datum WGS84; elev. <1 m). The nest was built on a sandbank along the exposed seashore on the edge of a mangrove forest (*Rhizophora mangle* and *Avicennia germinans*). Nest materials consisted of a mix of mollusk shells, rocks, sand, vegetation, and Mayan archeological remains (pottery fragments). Based on the mean incubation period estimated by Platt et al. (2008. J. Zool. 275:177–189: incubation period: 75 ± 11 days, range: 61–100 days), laying in the El Cuyo nest likely ocurred in early April 2007. Clutch size was 32: mean egg length was 74.4 ± 3.1 mm (range: 71.1–77.9 mm, N = 5), and mean egg width was

47.3 ± 0.5 mm (range: 46.5–47.8 mm). Only one hatchling had hatched, and it was 27.3 cm total length and weighed 100 g.

During nocturnal surveys on the road El Remate–Isla Arena, Campeche (20.53500°N, 90.37250°W, datum:WGS84; elev. <1 m.) in July 2008, we captured five *C. moreletii* hatchlings, one with the egg-tooth still present. Ferguson (1985. *In* Gans [ed.]. Biology of the Reptilia Vol. 4, pp. 329–341. John Wiley & Sons, New York) observed that the egg-tooth usually drops off during the first or second week of post-hatching development. Mean total length of hatchlings was 30.7 ± 2.3 cm (range: 28.9–34.7 cm) and mass was 70.4 ± 10.3 g (range: 60.0–90.0 g). Using the model of Platt et al. (2003. Herptol. Rev. 34:121–122) to calculate the age of *C. moreletii*, we estimated the incubation period at 92 ± 11 days. Thus, if these hatchlings belonged to aforementioned observed nest, oviposition would have been close to 11 April 2008.

Oviposition timing of *C. moreletii* we observed in Campeche is similar to that observed for *C. acutus*. Clutch deposition in *C. acutus* in México occurs from March to May, and hatching from June to August (Casas-Andreu 2003. Acta Zool. Mex. [n.s.] 89:111–128). In Belize, *C. acutus* also deposits eggs from March to May, and hatching occurs from June to July (Platt and Thorbjarnarson 2000. Copeia 2000:869–873). Based on habitat and oviposition date, our observations may represent at least one nest of a *C. moreletii* × *acutus* hybrid (Platt et al. 2008. J. Zool. 275:177–189). In the Yucatán Peninsula, the distribution of *C. acutus* remains poorly defined. Ernst et al. (1999. Cat. Amer. Amphib. Rept. 700:1–17) state that the distribution of *C. acutus* in the Gulf of Mexico begins in Tabasco, and hence, *C. acutus* may occur in Campeche and hybridize with *C. moreletii*. Ray et al. (2004. Cons. Genet. 5:449–462) determined that a region of hybridization between these two species exists in Belize, and Cedeño-Vázquez et al. (2008. J. Exp. Zool. 309A, *in press*) found an area of hybridization in Quintana Roo, México. These data may indicate that the Yucatán Peninsula represents a general zone of hybridization between *C. moreletii* and *C. acutus*.

We thank IdeaWild for providing equipment support. PAPIIT-DGAPA-UNAM (IN221208), CONACYT scholarship to AHEG (217838) and to SEPP (20299), and Dirección de la Reserva de la Biosfera Los Petenes provided financial support. We thank S. Platt and M. Hayes for editorial assistance.

TESTUDINES — TURTLES

ACTINEMYS* (= *CLEMMYS*) *MARMORATA (Western Pond Turtle)**. COURTSHIP BEHAVIOR.** Little has been published on the courtship behavior of *A. marmorata*. Here I contribute to the growing body of observations documenting courtship behavior with additional observations of courtship display and presumed mating in the wild accompanied by a series of photographs.

On 18 April 2008, while conducting herpetological surveys along Vaqueros Creek, a tributary to the Arroyo Seco River in Monterey County, California, J. Henricks and I observed two *A. marmorata* engaged in courtship activity in the depths of a ca. 1.5 m pool. Both turtles were located at the base of a bedrock slab that extended above water from the pool's rock/gravel substrate. The pair was first observed in the bottom of the pool facing each other. The female was facing away from us and had retracted her legs, but was anchored in place by her partially extended hind-limbs. The male was facing toward us, and was observed actively scraping/waving his forelimbs at the anterior marginal shields of the female's carapace, alternating between limbs and pausing briefly between bouts. At approximately 1446 h, the male noticed our presence and abandoned the female to surface, where he floated for several seconds to inspect us, head fully extended and making eye contact before diving and returning to the pool bottom where he resumed his courtship display. This ritualized courtship display was reinitiated for 35 seconds before the female attempted to reorientate herself away from the male, at which time the male swam around and repositioned himself to face the female, who resumed her earlier posture. This ritual of limb-waving (male), reorientation (female), and repositioning (male) continued several times until, at approximately 1452 h, the female had reorientated herself 180 degrees from her original position to face us. As soon as the female noticed our presence, she abandoned the male's advances and fled downstream, followed shortly by the male. The entire encounter lasted at least 6 minutes, 30 seconds (Figs. 1a–1d). These observations are loosely in accordance with *A. m. marmorata* courtship activity described in detail by Ashton (2007. Herpetol. Rev. 38:327–328), who described similar instances of ritualized behavior.

On 19 April 2008, while continuing herpetological surveys along a downstream portion of Vaqueros Creek, Henricks and I observed two *A. marmorata* in the act of mating. A third uninvolved *A. marmorata* was observed ca. 1 m upstream of the pair. The pair was first observed at 1412 h in the shallow waters (~ 10 cm) of

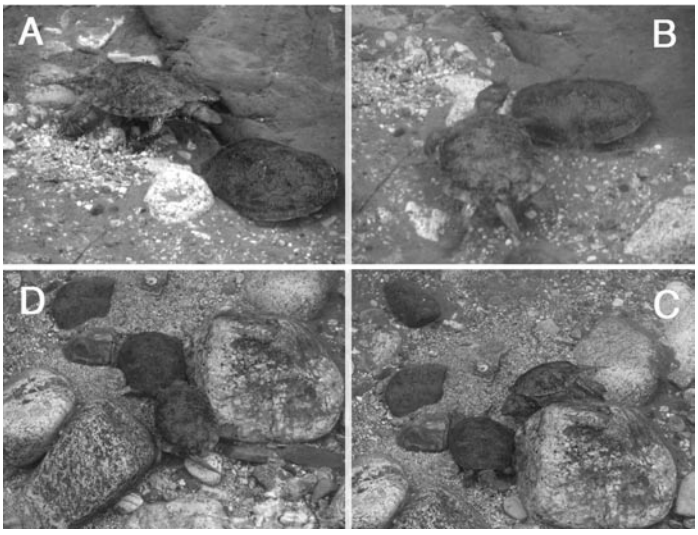

FIG. 1. Time-lapse series detailing ritual courtship display of *Actinemys marmorata*, depicting limb-waving (Fig. 1a), reorientation, and repositioning (Fig. 1b–1d).

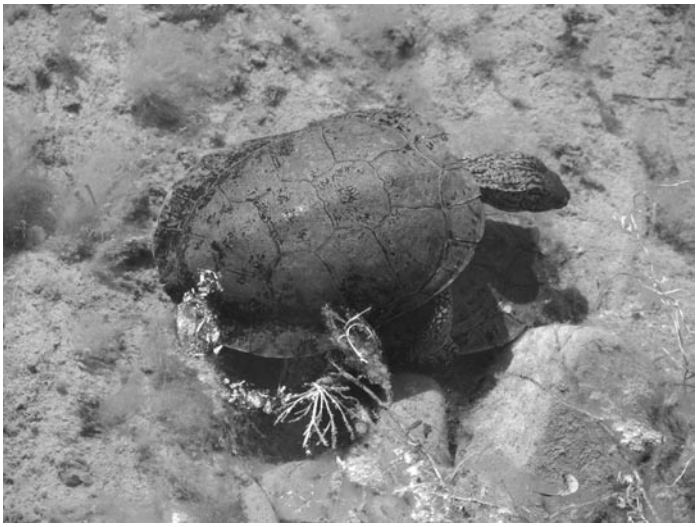

FIG. 2. *Actinemys marmorata* pair in the act of mating.

a bedrock and cobble-lined section of the creek, within 30 cm of the shoreline. The male had mounted the female at a ca. 45° angle; his forelimbs were firmly grasping the female's carapace near the fifth marginal shields, and his head was extended downward at a right angle toward the creekbed (Fig. 2). The male's tail was not visible from our elevated vantage point. The pair was observed so entwined for ca. 20 seconds before the male noticed our presence and extended his head above water to inspect us. Several seconds passed before, undeterred, the male lowered his head underwater and resumed mating until the female noticed our presence several seconds later and disengaged the male. All three turtles fled to the near bank and took cover beneath an algal mat.

Fieldwork was performed under contract with Chevron Pipe Line Company. Special thanks are in order to Chuck Trujillo and Chevron Pipe Line Company, landowner Lloyd Gould, Don Ashton, Jolie Henricks, and Justin Whitfield.

BRAZILIAN AMAZONIAN TURTLES. HABITAT. Very little is known about the habitat or distribution of the small non-riverine freshwater turtles that inhabit the Brazilian Amazon (Rueda-Almonacid et al. 2007. Las Tortugas y Cocodrilianos de los Países Andinos del Trópico. Conserv. Intern. Bogotá, D.C. – Colombia. 467 pp.). Although the ecology of some of these species is known for other parts of their wide distribution (e.g., *Kinosternon scorpioides* in Mexico, Colómbia, and coastal Brazil) their ecology and distribution within the Amazon Basin has been an enigma. There are records for single captures of *K. scorpioides* on a road in Roraima, near the Solimões River near Manaus, and in the Mamirauá Reserve near Tefé, but no populations were found. Similarly *Rhinoclemmys punctularia* has appeared sporadically on the road to Boa Vista from Manaus in Roraima, near Mindu igarapé in Manaus and near the Trombetas Reserve in Pará, but again no populations have been documented. We have collected *Phrynops gibbus* from shallow permanent forest pools in several different forests in the Amazon and can say with some confidence that they prefer shallow forest pools associated with buriti palms (*Mauritia* sp.), one of the principal fruits in their diet (Vogt et al., this report). It is also established (e.g., Pritchard and Trebbau. 1984. The Turtles of Venezuela. SSAR Contr. Herpet. 2, Ithaca, New York) that *Platemys platycephala* forages in ephemeral rain-filled forest pools throughout their range, and they are typically the only chelonian species found in these pools. Until now we have found only one species at any one time in the pools they inhabit.

On 22 April 2008 we visited forest wetlands 4000 m from the shore of the Amazon River within high evergreen rainforest near Tucumanduba, Municipality of Barreirinhas, Amazonas, Brazil (2.94575°N, 57.02408°W). We searched for turtles in seven different ponds ranging from 7 m to 50 m in diameter. The water was transparent and 20–30 cm deep. The substrate was covered with either grasses and/or decomposing leaves. The ponds were scattered within the rainforest and only a limited amount of light passed through the canopy to the ponds. The ponds are never connected, even at the height of the rainy season, and the flood waters of the Amazon River do not extend this far into the forest. However, water in the ponds filters out or evaporates in the dry season, and presumably the turtles either aestivate in the bottom of the ponds, in the forest, or move overland to a small forest stream (Sr. Bicó, pers. comm.). Turtles were collected by muddling with help of a local collector (Sr. Bicó). In addition to the turtles we captured, we also examined turtles that Sr. Bicó had previously taken in these ponds. We recorded the straight-line carapace length and mass of each turtle captured. This survey resulted in 27 *K. scorpioides*: seven adult males (mean CL 130.27 mm ± 10.55 and mean mass 288.57 g ± 71.05), 16 adult females (CL 129.24 mm ± 24.26 and 263.13 g ± 113.77) and four immatures (CL 65.05 mm ± 10.52 and 41.25 g ± 19.31); five *R. punctularia*: three immatures (CL 86.49 mm ± 11.84 and 105 g ± 47.67), one adult female (CL 113.63 mm and 280 g) and one male (CL 188 mm and 600 g); six *P. gibbus*: one immature (CL 85.61 mm and 70 g), one male (CL 181.41 mm and 530 g) and four females (mean CL 148.94 mm ± 27.67 and mean mass 500 g ± 247.11) and five *P. platycephala*: two immatures (mean CL 87.73 mm ± 28.74 and mass of 75 g) and three females (mean CL 129.97 mm ± 15.58 and mean mass of 260 g ± 98.49). All species reported were caught together in at least one of the ponds, and there was no evidence that any of these species was using one pond more than another. Analyzing fecal samples we observed that three of the four species had fed on plant material (fruits, seeds, leaves, and algae) while the *P. platycephala* had consumed only animal foods.

We thank Joelza for help with the fieldwork. This research was conducted under the auspices of CNPq and IBAMA's permit nº 14029-1.

CHRYSEMYS PICTA (Painted Turtle)**, *GRAPTEMYS GEOGRAPHICA*** (Northern Map Turtle)**, *TRACHEMYS SCRIPTA*** (Pond Slider). **AURAL ABSCESSES**. The incidence of aural

abscesses in turtles may be linked to various environmental factors such as organochlorine contamination via its effects on Vitamin A metabolism (Holladay et al. 2001. Ecotoxicol. Environ. Safety 48:99–106; Brown et al. 2004. J. Wildl. Dis. 40:704–712) or climatic conditions (e.g., excessive rainfall; Dodd and Griffey 2004. Herpetol. Rev. 35:233–235). Thus, aural abscesses may be an indicator of environmental stressors on turtle populations. It is therefore important to obtain a baseline for aural abscess prevalence in turtle populations to understand if changes in aural abscess frequencies are occurring and what might drive variation in their frequency over time or among populations (see also Gamble 2007. Chel. Conserv. Biol. 6:293–295).

We used a long-term mark-recapture dataset on a community of turtles from a lake in northern Indiana to examine aural abscess prevalence in three species, Painted Turtles (*Chrysemys picta*), Northern Map Turtles (*Graptemys geographica*), and Pond Sliders (*Trachemys scripta*). In addition, we were able to look for evidence of recovery from aural absesses.

Since 1979 we have nearly annually surveyed the turtle community in Station Bay in Dewart Lake, Kosciusko Co., Indiana, USA (41.37°N, 85.77°W) using box traps, fyke nets, basking traps, and dip nets (see Smith et al. 2006. J. Herpetol. 40:180–185 for details). Over the course of the study we have examined 1994 individually-marked Painted Turtles, 346 individually-marked Northern Map Turtles (plus 157 captures not marked), and 143 individually-marked Pond Sliders. Of the 1994 Painted Turtles, we observed four turtles with aural abscesses (0.2%). No Northern Map Turtles and Pond Sliders were observed with aural abscesses. All four of the Painted Turtles with aural abscesses were recaptured after the initial observation of the abscess. Three of these turtles were subsequently recaptured and the abscesses were gone.

Our observations suggest the incidence of aural abscesses is quite low in the Dewart Lake turtle community, and that turtles can recover from aural abscesses. The frequency of aural abscesses in *C. picta* that we observed is similar to the frequencies found in several populations of *C. picta* from Minnesota (Gamble 2007, *op. cit.*) and Iowa (Christiansen et al. 2004. J. Herpetol. 37:293–298). The only previous observations of aural abscesses in *T. scripta* and *G. geographica* also found no aural abscesses (Christiansen et al. 2004. J. Herpetol. 37:293–298). It thus appears that for many aquatic emydids, the natural frequency of aural abscesses is very low, and populations with higher frequencies of aural abscesses, as observed in some of the populations in Minnesota studied by Gamble (*op. cit.*), might indicate some sort of external stressor upon those populations.

We thank the many students, colleagues, and family members who have helped catch turtles at Dewart Lake. Funding was provided by Earlham College, Denison University, and our families. We thank Quaker Haven Camp (particularly T. and J. Dain) for housing, the Neffs and Mullens for storing equipment, and the late B. Haubrich for use of his pier.

EMYDOIDEA BLANDINGII (Blanding's Turtle). **CLUTCH SIZE.** Maximum clutch size for *Emydoidea blandingii* has been variously listed as 19 eggs (Congdon et al. 2008. Chel. Res. Monogr. No. 5, pp. 015.1–015.12), 21 eggs (Harding 1997. Amphibians and Reptiles of the Great Lakes Region. University of Michigan Press, Ann Arbor, Michigan. 378 pp.), or 22 eggs (Rowe 1992. Can. J. Zool. 70:1690–1695). Sajwaj et al. (1998. Final report to Non-game Wildlife Office, Minnesota Department of Natural Resources, Brainerd, Minnesota) lists 24 eggs and a maximum total clutch wet mass of 310 g in a central Minnesota population. Here, we report an observation of a female Blanding's Turtle from Anoka County, Minnesota that produced a single clutch of 23 eggs and a total clutch wet mass of 316.7 g.

On 28 June 2008 at 2145 h we observed an adult female *E. blandingii* (carapace length = 217.4 mm, plastron length = 198.5 mm) constructing a nest. The nest was constructed in sandy soil, ca. 185 m from water, and completed by 0300 h on 29 June 2008 (total lapsed time = 2 h 45 min). Nest depth was 172.0 mm, with an opening diameter of 133.5 mm at the top and 98.0 mm width near the bottom. Eggs at the top of the nest were covered by approximately 10 mm of sand. Mean egg mass was 13.8 g (SD = 0.6 g, range = 12.5–14.8 g), mean egg length was 35.36 mm (SD = 0.97 mm, range = 33.78–37.40 mm), and mean egg width was 24.78 mm (SD = 0.54 mm, range = 23.65–25.69 mm).

Clutch size of *E. blandingii* is highly variable (DePari et al. 1987. Can. Field-Nat. 101:440–442); mean clutch size differs geographically and ranges between 8.3–17.7 eggs (Sajwaj et al. 1998, *op. cit.*; Gibbons 1968. Can. J. Zool. 46:288–290). In *E. blandingii*, clutch size may increase with body size (Congdon et al. 2008, *op. cit.*), although Rowe (1992. Can. J. Zool. 70:1690–1695) and DePari et al. (1987. Can. Field-Nat. 101:440–442) did not observe this in Nebraska and Massachusetts populations, respectively. In a large southeastern Minnesota population (Weaver Dunes), mean clutch size was 9.8 and body mass of females averaged 1080 g; carapace length (CL) averaged 197.0 mm and mean egg size was 37.5 mm (length) × 23.5 mm (width). Eggs from this population averaged 12.7 g; mean total clutch wet mass was 112 g. Sajwaj et al. (1998, *op. cit.*) reported that adult Blanding's Turtles in a central Minnesota population (Camp Ripley) are substantially larger than other known populations (males = 2440 g, 260.3 mm CL; females = 2210 g, 244.6 mm CL,) and this population has produced the largest mean clutch size (17.7), several large clutches of 23–24 eggs, and a maximum single clutch mean egg weight of 16.3 g. The current nesting site, near Carlos Avery Wildlife Management Area, is 151 km SE of Camp Ripley and 135 km NW of Weaver Dunes. Despite the moderate size of the nesting female and typical egg dimensions described herein, this female apparently produced the largest total clutch wet mass recorded for *E. blandingii*.

We thank Evan and Nancy Whitby for access to the nesting site and for originally alerting us to the nesting activity.

GRAPTEMYS OCULIFERA (Ringed Map Turtle). **FORAGING BEHAVIOR**. Species in the emydid turtle genus *Graptemys* are highly aquatic, yet dietary studies indicate occasional consumption of terrestrial insects to complement the more typical aquatic prey, which may include insect larvae, snails, clams, mussels, sponges, bryozoans, and algae (e.g., Kofron 1991. Amphibia-Reptilia 12:161–168; Lindeman 2000. Can. J. Zool. 78:992–1008; Lindeman 2006. Chel. Cons. Biol. 5:25–31; Shealy 1976. Bull. Florida St. Mus. Biol. Sci. 21:47–111; Webb 1961. Amer. Midl. Nat. 65:193–214). Insects may be taken after they fall to the water's surface, but terrestrial feeding by *Graptemys* has not been described. Here I detail observations of one or more male *G. oculifera* repeatedly searching for and taking insects from their terrestrial perches on a floating log.

On the morning of 25 May 2008 I observed a group of *G. oculifera* basking on a floating log lodged behind erosion-control structures beneath the Interstate 59 crossing of the West Pearl River (St. Tammany Parish, Louisiana, USA). From a shaded location on shore ca. 25 m from the log, I used a spotting scope with 30× magnification and built-in digital camera to observe basking by at least six different individuals. Initially, a male was observed straddling the log in a typical basking orientation with neck extended and head up, facing the shore. A small (ca. 1 cm long) winged insect crawled toward the male, made brief contact with the anterior edge of his plastron, and retreated. The male appeared to take no notice of the insect until this contact, then it looked down and quickly grasped the insect in its mouth and re-entered the water. In subsequent observations, a turtle (possibly the same male) was observed facing the log, holding its head above the level of the log. The turtle sometimes sat in this position for several seconds before either submerging or pulling itself up on the log with its forelimbs. On six occasions I observed the turtle pull itself up partway onto the log as if initiating a basking session, but then quickly dropping back into the water before coming completely out of the water; on two of these occasions, it was observed to make quick strikes to take insects from the log, presumably consuming them under water. The insects were unidentified but may have been wasps, based on constrictions observed at their abdomens.

Cagle (1953. Zoologica 38:137–144) observed two *G. oculifera* swimming against the current and straining to extend their mouths toward a log, at a point above the waterline, apparently to feed. Carr (2008 Southeast. Nat. 7:748–752) described repeated brief terrestrial foraging forays made by *G. pseudogeographica* along a riverbank in Louisiana. He interpreted those turtles' actions as directed at eating herbaceous plants. My observations suggest that terrestrial insects might also have been a target of their foraging behavior. Cagle's and Carr's observations and those detailed here document terrestrial feeding behavior that might explain the origin of some of the terrestrial insects included in dietary samples from species of *Graptemys*. I thank W. Selman for comments on the manuscript.

MALACLEMYS TERRAPIN TERRAPIN (Northern Diamondback Terrapin). **CONJOINED INDIVIDUALS**. On 13 September 2007, two conjoined Northern Diamondback Terrapin hatchlings were found at Jamaica Bay Wildlife Refuge, a unit of the Gateway National Recreation Area, Queens County, New York, USA (Fig. 1). They were found on a trail, lying on their carapaces, apparently unable to right themselves. The timing and location of this find suggests that they came from one of the few nests in this area to avoid predation, incubated naturally, successfully emerged from the nest, and walked at least a short distance.

FIG. 1. Photograph of conjoined *Malaclemys t. terrapin* on 13 September 2007, the day they were discovered by a visitor of Jamaica Bay Wildlife Refuge Queens New York. Photo by ELR.

They are being raised at Cold Spring Harbor Fish Hatchery in Cold Spring Harbor, New York. The hatchlings each have two forelimbs, but share hindlimbs. There are also two tails, one larger than the other. Radiographs indicated that the terrapins are joined at the pelvis or just anterior to the pelvis (Fig. 2). The right hatchling seemed underdeveloped and was the weaker of the two. They weighed 6.19 g. The right individual had a 21.9 mm carapace length (measured from nuchal to the shared pygial);

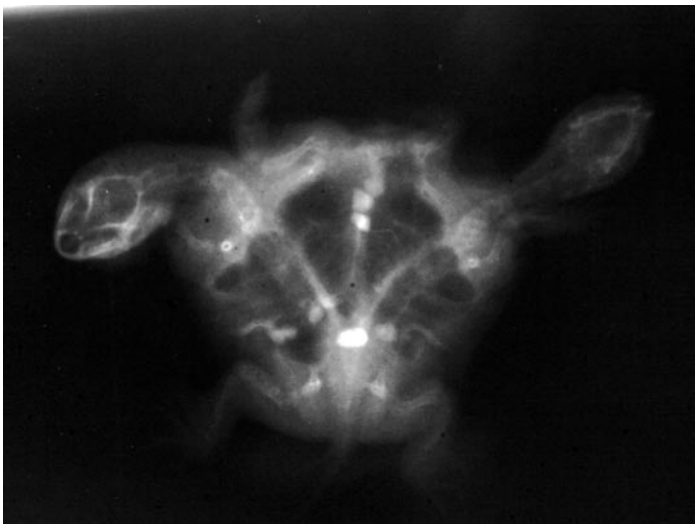

FIG. 2. Radiograph of conjoined *Malaclemys t. terrapin* on 22 July 2008, illustrating attachment at or just anterior of the pelvis.

20.1 mm plastron length; head width of 6.5 mm; and 7 left and 12 right marginal scutes. The left individual had an 18.9 mm carapace length; 20.1 mm plastron; head width of 7.7 mm; and 6 right and 12 left marginal scutes. Combined, measured down the middle, the carapace length was 22.6 mm; the plastron was 24.0 mm; the two tails measured 9.8 and 5.0 mm, respectively.

Approximately a month after they were discovered, 11 November 2007, the right hatchling had developed more and was starting to take more control in combined movements. They were alive and feeding on 11 August 2008.

MAUREMYS RIVULATA (Balkan Terrapin). **TOURIST HABITUATION AND DIET**. Although *Mauremys rivulata* is known to tolerate human-modified habitats, and remains locally abundant, it is generally wary and most easily observed from a distance. The species is omnivorous, and bread has been noted in diet summaries since 1899 (Loveridge and Williams 1957. Bull. Mus. Comp. Zool. Harvard, 115, 557 pp.; Valakos et al. 2008. The Amphibians and Reptiles of Greece. Ed. Chimaira, Frankfurt am Main, 463 pp.).

On 24 June 2008, I witnessed several dozen Balkan Terrapins converge just below the downstream side (on the in-bound lane of the roadway above) of the bridge on the western outskirts of Skala Eresou on Lesvos Island, Greece, in response to the stopping of a tour bus on the bridge above the water course. The tour bus had paralleled the water course for several kilometers prior to stopping on the bridge, and appropriate aquatic habitat for this species was clearly available for some distance upstream. When, however, the driver tossed bread fragments into the water below, terrapins began to arrive in substantial numbers (Fig. 1) from both up- and downstream. Competition for the bread was, at times, violent and often involved several terrapins. Uwe Fritz (Museum of Zoology, Dresden, pers. com.) reported seeing similar behavior in western Crete and had heard of similar tourist habituation in this species in areas along the south coast of Turkey. These observations suggest that this behavior probably occurs at a number of tourist sites within the range of *M. rivulata*, but has gone unreported until now.

Submitted by **STEPHEN D. BUSACK**, 348 Belmeade Road, Rochester, New York 14617, USA; e-mail: sbusack348@aol.com.

PSEUDEMYS GORZUGI (Rio Grande Cooter). **KYPHOSIS.** Kyphosis (abnormal convex curvature of the spine) has been reported in several chelonian families, including several emydids, and may result from a variety of environmental factors and ontogenetic miscues (Plymale et al. 1978. Southwest. Nat. 23:457–462). On 17 June 2008, I captured a distinctly kyphotic adult *P. gorzugi* (Fig. 1) in the Black River at Black River Village, Eddy County, New Mexico, USA (32.22327°N, 104.21791°W; WGS 84). The apex of the carapace was slightly left of the midline at the junction of the second and third vertebral scutes, suggesting kyphoscoliosis similar to that reported for *Trachemys g. gaigeae* in New Mexico (Stuart and Painter 2008. Herpetol. Rev. 39:218–219). Scutellation was abnormal with regard to shape of vertebral and costal scutes, and two extra left costals were present posterior to C3. The ratio of shell height to carapace length was 0.54, shell height to carapace width was 0.68, and carapace width to carapace length was 0.80. The cooter appeared to be healthy and was released alive. This is the first report of kyphosis in *P. gorzugi*.

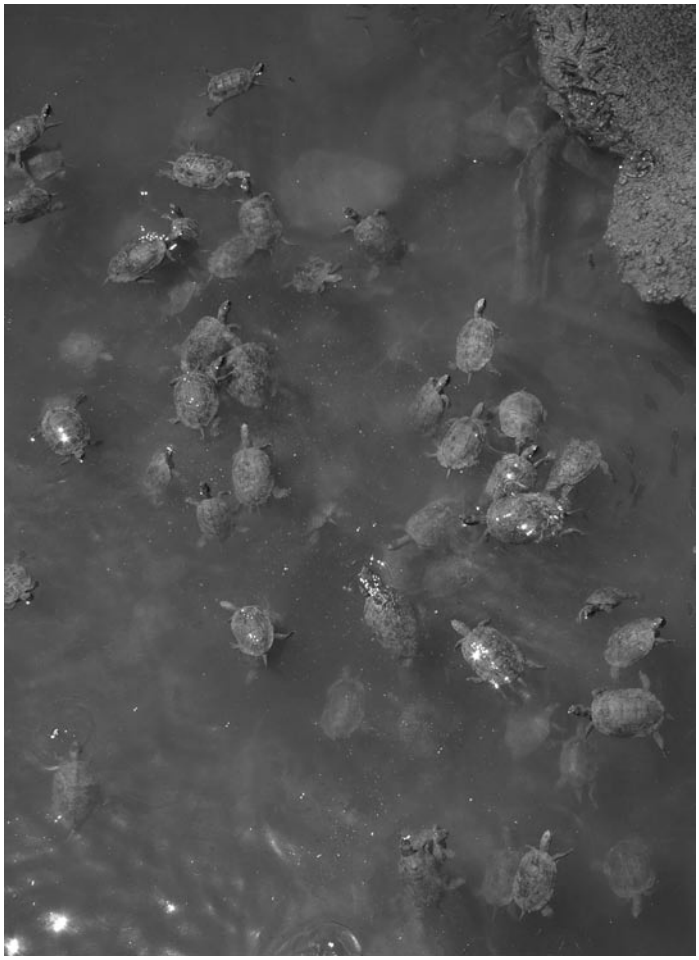

FIG. 1. *Mauremys rivulata* aggregation in response to tourist-provided bread.

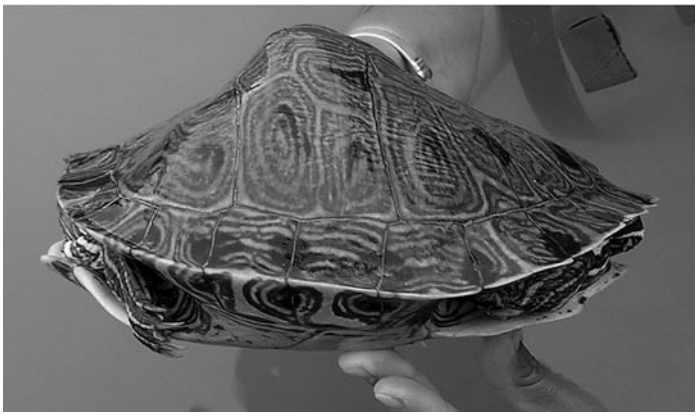

FIG. 1. Kyphotic *Pseudemys gorzugi* from Eddy County, New Mexico.

I thank Charles Painter and James Stuart for their helpful advice.

Submitted by **NIKOLAS D. ZYMONAS**, New Mexico Department of Game and Fish, Conservation Services Division, P.O. Box 25112, Santa Fe, New Mexico 87504, USA; e-mail: Nik.Zymonas@oregonstate.edu.

TERRAPENE CAROLINA (Eastern Box Turtle) and ***GOPHERUS POLYPHEMUS*** (Gopher Tortoise). **INTERSPECIFIC INTERACTION**. *Terrapene carolina* has been documented to use burrows constructed by *Gopherus polyphemus* (e.g., Brodie 1959. Herpetologica 15:101–102; Landers and Speake 1980. Proc. Ann. Conf. Southeast. Assoc. Fish Wildl. Agencies 34:515–529; Brandt et al. 1993. Herpetol. Rev. 24:4). However, we are unaware of any field reports describing social interactions between these two species.

Using a video camera and an automated time-lapse VHS tape recorder, we observed an interaction between an Eastern Box Turtle and a Gopher Tortoise at the Camp Shelby Joint Forces Training Center (CSJFTC) in Forrest County in southern Mississippi, USA. On 2 August 2006 at 8:48:11 h (CST; ambient air temperature = 30ºC), an adult female Gopher Tortoise (carapace length = 267 mm) that was sitting in front of her burrow rapidly (~1 sec) retreated into it as if she had been disturbed. Seven seconds later, an adult Eastern Box Turtle entered into camera view, ~0.5 m behind the burrow entrance. After briefly pausing just behind the burrow, the Box Turtle walked onto the bare soil in front of the burrow entrance and faced the burrow mouth from a distance of ~0.5 m. The Box Turtle then incrementally advanced toward the burrow. Shortly after reaching the burrow mouth, the Box Turtle made several backward and forward movements starting at 8:54:56. At this point, the front of the Box Turtle was partially inside the burrow and out of camera view, making it difficult to determine what the turtle was doing. At 8:56:00, or about 64 sec after the Box Turtle started moving backward and forward in the burrow entrance, the female Gopher Tortoise emerged from her burrow as she pushed the Box Turtle with her gular. For the next 17 sec, with her head withdrawn, the tortoise repeatedly rammed and nudged the box turtle, pushing it backward and against the side of the burrow entrance. However, even as the tortoise pushed against it, the Box Turtle appeared to try to enter the burrow. During this exchange, both animals moved forward and backward, but it was unclear whether the Box Turtle was actually pushing the tortoise or whether the tortoise's backward movements were voluntary or partially due to the slope of the burrow entrance. The Gopher Tortoise then backed slightly into her burrow, and the movements of both turtles briefly decreased in intensity. About 25 sec later, the physical aggression resumed in much the same manner and intensity as before (but mostly with the tortoise further inside her burrow and out of camera view). The camera observed this aggressive bout for ~50 sec until the Box Turtle completely entered the burrow at 8:57:32 h, or about 2 min and 36 seconds after the physical interaction appeared to begin (based on the Box Turtle's initial backward and forward movements before the tortoise emerged into camera view). At 10:38:30 h, the tortoise emerged and sat on her apron for 40 min before going back into her burrow. The tortoise emerged once again at 12:19:01 h, sat on her apron for 37 min and again reentered her burrow. At 13:31:20 h, while the tortoise was still in its burrow, the box turtle emerged and then left the filmed area. Events such as this one are probably infrequent and/or difficult to observe, as Gopher Tortoises tend to flee into their burrows when humans approach. It is unclear why the Box Turtle was so determined to enter this particular Gopher Tortoise burrow, but tortoise burrows may provide Box Turtles with foraging opportunities (Landers and Speake, *op. cit.*) or shelter from temperature extremes and arid conditions (Dodd 2005. Iguana 12:153–159). Although we have no evidence to support this, it is possible that the Gopher Tortoise was simply defending its burrow, a structure that is a key feature in the species' daily activities. Interestingly, although we are unaware of any previous accounts describing naturally occurring aggression between these two species, Wailes (1854. Report on the Agriculture and Geology of Mississippi. E. Barksdale, State Printer, Jackson, Mississippi) describes how hunters in Mississippi would capture Gopher Tortoises by exploiting the aggressive response of tortoises toward Box Turtles placed into their burrows. He writes: "A common box terrapin [turtle] is used for the purpose, being sent into the gopher's [tortoise] hole, from which he is speedily driven out; but, in the eagerness of pursuit, the gopher frequently follows him so far above ground as to be cut off from his retreat and captured by the waiting hunter." Together, Wailes' (*op. cit.*) account and our observation suggest that Gopher Tortoises may respond aggressively with some regularity to Box Turtles that visit their burrows.

We thank T. Borries, A. Holbrook, D. Jackan, J. Lee, B. Madden, A. Portoluri, J. Smolinsky, N. VandenBroek, and the staff at The Nature Conservancy Camp Shelby Field Office for valuable assistance in the field. D. Pike and J. Smolinsky provided helpful comments on this manuscript. J. Lee and S. Rosso brought Wailes' (1854) account to our attention. We also thank the Mississippi Army National Guard for their continued support of tortoise conservation efforts on CSJFTC. The U.S. Army Construction Engineering Research Laboratory funded this research.

TERRAPENE ORNATA (Ornate Box Turtle). **HABITAT.** *Terrapene ornata* is found from southern Wyoming to western Indiana, south to Louisiana and southeastern Arizona into north-central Mexico (Degenhart et al. 1996. Amphibians and Reptiles of New Mexico. University of New Mexico Press, Albuquerque, New Mexico. 431 pp.). In southeastern Arizona, the species is found primarily in flatlands and low valleys within Semidesert Grassland, Chihuahuan Desertscrub, and lower Madrean Evergreen Woodland (Brennan and Holycross 2006. Amphibians and Reptiles in Arizona. Arizona Game and Fish Department, Phoenix, Arizona. 150 pp.). Within these communities, it seeks sites where the soil is sandy or otherwise suitable for burrowing (Stebbins 2003. A Field Guide

to Western Reptiles and Amphibians. Houghton Mifflin, Boston, Massachusetts. 336 pp.). According to Degenhart et al. (*op. cit.*), *T. ornata* does not typically occupy dense woodlands.

We have noted an apparently disjunct population of *T. ornata* along the lower San Pedro River near the town of Dudleyville, Arizona, inhabiting riparian woodland consisting primarily of an overstory of Fremont Cottonwood (*Populus fremontii*) and Goodding's Willow (*Salix gooddingii*). In 2004, we discovered box turtles inhabiting a non-native dominated plant community within the floodplain of the Gila River, ca. 14.5 km downstream and north of Dudleyville (UTM 12S 0514736, 3651967). This area is predominately dense saltcedar (*Tamarix* sp.) with interspersed Mesquite (*Prosopis velutina*) at the ecotone with the Sonoran Desert upland community. Isolated cottonwoods and willows can be found along the active channel of the Gila River. Overall, canopy cover measured with a hand-held densiometer was 88.4%. Based on ocular estimates, ground cover was 29.4% silt/sand, 34.5% saltcedar duff, 29.7% downed branches and logs, 5.6% herbaceous material, and trace amounts of rock. Saltcedar tree height was >6 m. We subsequently captured and affixed radio transmitters to seven turtles (2 females, 5 males) for a home range study. Vegetation density made it extremely difficult to walk through the area and record locations. Dens and forms were easily constructed in the sandy substrate and often were under dense piles of downed saltcedar branches or covered with duff. We know of no other reports of Ornate Box Turtles inhabiting extensive, dense stands of this non-native plant. It is widely believed that the regulated flows from the upstream Coolidge Dam resulted in conditions favorable to invasion by saltcedar. The lower San Pedro River is free flowing.

TRACHEMYS ADIUTRIX **(**Capininga). **DIET.** The diet of *Trachemys adiutrix* is not known. We examined stomach contents of specimens collected on Curupu Island, Maranhão State, Brazil, (2.4025°S, 44.11444°W) situated about 30 km off of São Luís in the inner part of São José Bay. This species frequently inhabits the small freshwater lagoons that occur between dune systems.

Trachemys adiutrix were captured from September 2003 to June 2005 with handcrafted traps, which are manufactured locally using wood stems and are similar to lobster traps. Every 15 d, one baited trap (containing small pieces of chicken and beef) was placed in each of the lagoons for two consecutive daylight hours. We verified sex by measuring tail length and palpating the inguinal region, and carapace length (CL) was measured with calipers to the nearest 0.1 cm. As the relationship between age and size is unknown for *T. adiutrix*, two size classes were arbitrarily established (after Balensiefer 2003. Unpubl. master's thesis, Departamento de Ecologia. INPA/UFAM. Manaus, Amazonas. 60 pp.): small (7.4–11.5 cm CL) and large (11.6–19.0 cm CL). Individuals within each size class were then subdivided into males and females.

Stomach contents were collected from 63 individuals; seven individuals were excluded from analyses because their stomachs contained only unidentified material. Stomachs were flushed within a few minutes of capture and afterwards all individuals were released at their point of capture. The extracted material was collected with forceps, placed in a plastic fine-woven sieve, and then removed with a brush and fixed with 70% ethanol. Food items were first categorized as either plant or animal material. Plant material was further subcategorized as leaves, roots, seeds, macroalgae, or bryophytes. Animal material was subdivided into fishes, insects, or arachnids. All unidentifiable material was categorized as "unidentified." We measured the volume of the stomach contents using volumetric displacement in a graded test tube.

We observed that about 50% of total stomach content volume was plant material and 50% was animal material. For the females (N = 28), total percent volume was 22% of animal material and 31% of plant material. For the males (N = 28), total percent volume was 25% of animal material and 22% of plant material. Small turtles, ranging from 7.4–11.5 cm CL, consumed primarily fish and plant matter. Individuals in the large class (11.6–19 cm CL) consumed more vegetation than animal matter. Plant material comprised 31% of consumed food items for female *Trachemys adiutrix* compared to 22% for that of males. Animal matter was observed in 22% and 25% of female and male stomachs respectively, consisting of fish, insects and arachnids. However, our study was not conclusive with respect to selective feeding in natural habitats because we did not measure food availability in the ponds.

SQUAMATA — LIZARDS

ALEXANDRESAURUS CAMACAN (Alexandre's Lizard; Calanguinho do Alexandre). **REPRODUCTIVE BEHAVIOR**. Reports on lizard mating behavior are relatively scarce and most such data come from observations recorded in captivity. Data are even less frequent for secretive lizards. Such is the case for the Gymnophthalmidae, an assemblage of >200 Neotropical species representing 43 genera and four subfamilies (Rodrigues et al., Amer. Mus. Novit., *in press*; Rodrigues and Silva 2008. Zootaxa 1873:50–60). One of the latter, the subfamily Gymnophthalminae, comprises 16 genera of mostly secretive fossorial lizards living in forested or open areas (Pellegrino et al. 2001. Biol. J. Linn. Soc. 74:315–338; Rodrigues et al. 2005. Amer. Mus. Novit. 3565:1–27). Hence, we provide the first report of the copulatory behavior in the gymnophthalmine *Alexandresaurus camacan*, which occurs along the Atlantic Rainforest state of Bahia, from São Sebastião do Passé in the north (Freitas et al. 2007. Herpetol. Rev. 38:481) to Una in the south (Rodrigues et al. 2007. Amer. Mus. Novit. 3565:1–27).

At ca. 1250 h on 15 February 2006, we observed and photographed a mating pair of *A. camacan* in the forest surrounding experimental fields of the Cacao Research Center, CEPEC/CEPLAC, at Ilhéus, state of Bahia, Brazil (14.75°S, 39.22°W; datum WGS84; near sea level). The pair was concealed under a fallen large bromeliad (genus *Aechmea*) in a cacao plantation shaded by

FIG. 1. A mating pair of *Alexandresaurus camacan*, Bahia, Brazil.

Erythrina and other large trees of the remnant primary forest. The lizards were copulating in the leaf litter under the leaves of the bromeliad and remained immobile after exposure and during the next 5 min when we took pictures of the mating pair. The male mounted the female on the latter's left side grasping her with his right hind leg and biting the dorsal part of her neck. Fig. 1 reveals the right hemipenis still everted, likely the one used. The right side of female cloaca was visibly swollen. The figure reveals that the tails of both specimens were intact, that the male was larger and much more brightly colored than his mate, having yellowish flanks mottled with black and an irregular longitudinal series of white dots, whereas the female had almost homogeneous brown flanks.

The belly-to-back copulatory position with the male biting and gripping the skin of female´s neck was reported for several lizards like *Phrynosoma* and is apparently widespread in lizards (Sherbrooke et al. 2005. Herpetol. Rev. 36:64–65), but has never previously been reported among the Gymnophthalmidae.

Submitted by **CARLOS JARED** (e-mail: jared@usp.br)**, MARTA MARIA ANTONIAZZI** (e-mail: mmantoniazzi@butantan.gov.br)**,** Laboratório de Biologia Celular, Instituto Butantan, Av. Vital Brasil 1500, CEP 05503-900, São Paulo, Brazil; and **MIGUEL TREFAUT RODRIGUES**, Universidade de São Paulo, Instituto de Biociências, Departamento de Zoologia, Caixa Postal 11.461, CEP 05422-970, São Paulo, Brazil (e-mail: mturodri@usp.br).

AMEIVA FUSCATA (Dominican Ground Lizard). **ARBOREAL ACTIVITY AND DIET.** Lizards in the genus *Ameiva* are generally terrestrial and facultatively omnivorous (Henderson and Powell 2009. Natural History of West Indian Reptiles and Amphibians. University Press of Florida, Gainesville; *in press*). From 4–23 June 2008, near the mouth of the Batali River on the leeward (western) coast of Dominica (15.452°N, 61.446°W), we observed three small *A. fuscata* (SVL 70–100 mm) climb to heights in excess of 1.5 m on trees. One arboreal *A. fuscata* appeared to be stalking an *Anolis oculatus*. Arboreal activity was described previously for *A. alboguttata* and *A. pleii* (Powell and Censky 2002. Herpetol. Rev. 33:50), the former tracking a trail of ants up a tree trunk.

Ameiva fuscata fed regularly on the pulp of fallen mangoes, but did not feed on the carcass of a dead *A. fuscata* adjacent to an area of intense activity. That lizards ate fallen mangoes confirmed descriptions that *Ameiva* are dietary generalists (e.g., Powell et al. 2005. The Reptiles and Amphibians of the Dutch Caribbean. St. Eustatius National Parks Foundation, Gallows Bay, St. Eustatius, Netherlands Antilles. 192 pp.). That they did not feed on the carcass of a dead *Ameiva* was surprising, as *A. fuscata* is known to eat eggs, embryos, and hatchlings of *Iguana delicatissima* (Breuil 2002. Patr. Nat., Paris 54:1–339; Knapp 2007. Iguana Spec. Grp. Newsl. 10[2]:13–14; A. Mitchell in Henderson and Powell, *op. cit.*), hatchling *Eretmochelys imbricata* (Knapp and Prince 2008. Herpetol. Rev. 39:213–214), and scavenge carrion and meat scraps (Malhotra and Thorpe 1999. Reptiles & Amphibians of the Eastern Caribbean. Macmillan Educ. Ltd., London. ix + 134 pp.; L. A. White and R. W. Henderson in Henderson and Powell, *op. cit.*).

Arlington James, Forest Officer, Forestry, Wildlife, and Parks Division, Ministry of Agriculture & the Environment, Commonwealth of Dominica, was instrumental in issuing permits to conduct research in Dominica and facilitated our efforts in myriad ways. Protocols were approved by the Avila University Animal Care and Use Committee. Fieldwork was funded by a grant from the National Science Foundation (USA) to Robert Powell (DBI-0242589).

ANOLIS CRISTATELLUS (Crested Anole). **AVIAN PREDATION**. The Pearly-eyed Thrasher (*Margarops fuscatus*) opportunistically feeds on eggs and chicks of parrots and other forest birds (Arendt 2000. Ornithol. Neotropical 11:13–63; Lazell 2005. Island: Fact and Theory in Nature. Univ. California Press, Berkeley), and is an important predator of *Anolis* lizards (Waide and Reagan 1983. Amer. Nat. 121[1]:133–138). In a review of avian predators of West Indian reptiles, Powell and Henderson (2008. Iguana 15[1]:9–11) recorded only two birds taking *A. cristatellus*, both falconiform raptors. Here I report Pearly-eyed Thrasher predation on the Crested Anole on Guana Island, British Virgin Islands (18.46666°N, 64.58333°W; WGS 84).

On 23 Oct 2007 ca. 1800 h, a young male *A. cristatellus* jumped onto a roof (3 m long, 1 m wide, 2.5 m above ground, and in contact with the vegetation canopy alongside) often used by the species for basking. Unusually, it made a noisy landing. Anoles use flight behavior to deter snake predation (Leal and Rodriguez-Robles 1997. Anim. Behav. 54:1147–1154). This anole quickly ducked under the eve of the roof, followed within 5 sec by the arrival of a thrasher. The bird appeared to be searching for the lizard, located it, but was not able to catch it. In the next few seconds, the bird ran quickly along the roof edge back and forth twice, head looking down, neck cocked sideways, and beak extended below the eve.

It was apparently following the lizard under the eve. It eventually drove the anole out onto the wall. Whether the anole was herded or stopped from escaping by the bird was not clear because I could not see under the eve. Once in the open, the bird caught the lizard in its beak. The lizard struggled and the thrasher took at least 5 min to subdue and swallow it. In addition to falconiform raptors, the snake (*Alsophis portoricensis*) and mongoose (*Herpestes javanicus*) also prey on the Crested Anole (Platenberg and Boulon 2006. J. Appl. Herpetol. 3[3]:215–235; Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies: Descriptions, Distributions, and Natural History. Univ. Press Florida, Gainesville. 720 pp.).

Submitted by **WENHUA LU**, The Conservation Agency, 6 Swinburne Street, Jamestown, Rhode Island 02835, USA; e-mail: hq@theconservationagency.org.

CNEMIDOPHORUS OCELLIFER (Spix's Whiptail). **ATTEMPTED PREDATION**. The *Cnemidophorus ocellifer* complex is a widespread group of teiid lizards found in open habitats in Brazil south to the Amazon (Peters and Donoso-Barros 1970. Catalogue of the Neotropical Squamata. Part II. Lizards and Amphisbaenians. Bull. U.S. Natl. Mus. 297:1–293; Vanzolini et al. 1980. Répteis da Caatinga. Acad. Brasil. Ciênc., Rio de Janeiro, Brazil. 161 pp.). Though at least six species from this complex have been recently described (e.g., Feltrim and Lema 2000. Biociências, Porto Alegre 8:103–114; Colli et al. 2003. Occ. Pap. Oklahoma Mus. Nat. Hist. 14:1–14; Colli et al. 2003. Herpetologica 59:76–88), the epithet *ocellifer* continues to be applied as a general tag to populations in the complex. Mesquita and Colli (2003. J. Herpetol. 37:498–509) studied the diet of *C. ocellifer* and reported termites, spiders, grasshoppers, and insect larvae as the most frequent prey. These results generally agreed with Vitt (1991. J. Herpetol. 25:79–90), who found termites to be the most important prey. Here, we add to dietary data on *C. ocellifer* with the observation of an attempt at saurophagy.

On 20 March 2006, we observed a predation attempt by an adult *C. ocellifer* (53.3 mm SVL) on a small juvenile *Tropidurus hygomi* in Mata de São João municipality, Bahia State, Brazil (12.5406°S, 37.9986°W; datum WGS84; elev. 20 m). Vegetation consisted of xeromorphic coastal forest, a type of restinga, an ecosystem characterized by medium-sized trees and shrubs adapted to dry, sandy, acidic, and nutrient-poor soils. RMLS was pursuing the *T. hygomi* when the *C. ocellifer* attacked it and bit off a 31.9 mm piece of its tail. After autotomizing its tail, the *T. hygomi* escaped. The *C. ocellifer* was captured, euthanized, and dissected. Besides the tail of *T. hygomi*, we found the following partly digested prey: two adult spiders (Arachnidae) belonging to different species, an adult ant (Formicidae), an adult grasshopper (Acrididae), and one larval ant lion (Myrmeleontidae). This is the first record of saurophagy in *C. ocellifer*.

The *C. ocellifer* and its prey were deposited in the herpetological collection of the Museu de Zoologia da Universidade de São Paulo, São Paulo, Brazil (MZUSP 98027, Miguel T. Rodrigues field number MTR 12557).

We thank Silvio Shigueo Nihei for identifying the arthropods and M. Hayes for the editorial suggestions.

SANTOS** (e-mail: santosrml@hotmail.com), Departamento de Genética, Instituto de Biociências, Universidade de São Paulo; **JOSÉ CASSIMIRO** (e-mail: geckoides@yahoo.com.br), and **MIGUEL TREFAUT RODRIGUES** (e-mail: mturodri@usp.br), Departamento de Zoologia, Instituto de Biociências, Universidade de São Paulo, Caixa Postal 11.461, CEP 05422-970, São Paulo, SP, Brazil.

COLEODACTYLUS NATALENSIS (NCN). **CLUTCH SIZE; HATCHLING SIZE.** *Coleodactylus natalensis* is a small lizard endemic to the Atlantic Forest of Rio Grande do Norte, Brazil (Freire 1999. Bol. Mus. Nac. 399:1–14). Clutch size is not known, but its geographically proximate congener, *C. meridionalis*, has a one-egg clutch (Vanzolini et al. 1980. Répteis das Caatingas. Acad. Bras. de Ciênc. Rio de Janeiro, Brazil. 161 pp.). Here, we provide an observation of clutch size and hatchling size in *C. natalensis*.

At 1630 h on 24 January 2006, PAGS collected two eggs of *C. natalensis* ca. 1 m apart among leaf litter in a 30-cm deep cavity in a rock (1 m^2) at the Estação Experimental Rommel Mesquita de Faria (Mata do Jiquí; 05.9305ºS, 35.1814ºW, datum: WGS84; elev. 40 m), an Atlantic Forest fragment on an EMPARN (Empresa de Pesquisas Agropecuárias do Rio Grande do Norte) farm of 79 ha in the of municipality Parnamirim. These data and field observations of females carrying one egg (CMCAL, pers. obs.) indicates that this species likely has a fixed clutch size of one egg.

The eggs were placed in a terrarium (20 × 12 × 20 cm) with a substrate of sand and leaf-litter, and maintained at Laboratório de Herpetologia, in the Departamento de Botânica, Ecologia e Zoologia in Universidade Federal do Rio Grande do Norte) at an ambient temperature averaging about 25ºC, but which varied between 24ºC and 32ºC over the incubation period. On 6 March 2006 (41 days after collection), one juvenile emerged. Measurements were SVL: 11 mm; tail length: 0.8 mm; foreleg length: 3.1 mm; fourth finger: 0.4 mm; hindleg length: 3.6 mm; fourth toe: 0.7 mm; head length: 2.9 mm; head width: 2.0 mm; jaw length: 1.6 mm; head height: 1.1 mm; body width: 2.2 mm; pelvis width; 1.3 mm; axilla-groin length: 4.4 mm; and mass: 0.024 g. This is the first record of hatchling size in *C. natalensis*.

The specimen was deposited in the Herpetological Collection of Universidade Federal do Rio Grande do Norte (CHBEZ 1504), municipality of Natal. We thank two anonymous reviewers for suggestion on the manuscript. Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) provided research grants to LBR (process 141993/2006-5) and to PAGS (process 107762/2006-4).

DIPLOGLOSSUS BILOBATUS (O'Shaughnessy's Galliwasp). **REPRODUCTION.** *Diploglossus bilobatus* is a diurnal, secretive anguid known from lowlands and adjacent premontane slopes of Costa Rica and Panama (Savage 2002. The Amphibians and Reptiles of Costa Rica. A Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago, Illinois. 934 pp.). Taylor (1956. Univ. Kansas Sci. Bull. 38:3–222) reported clutches of six and 15 eggs. The purpose of this note is to provide additional information on reproduction of *D. bilobatus*.

Five males (mean SVL = 82.4 mm ± 3.1 SD, range = 78–86 mm, LACM 130923, 148115, 116, 121, 122); three females (mean SVL = 68.0 mm ± 7.0 SD, range = 61–75 mm, LACM 148114, 119, 120) and five presumed neonates (mean SVL = 27.6 mm ± 2.1 SD, range = 25–30 mm, LACM 148117, 123, 124, 126, 127) collected 1962 to 1994 in Costa Rica (10°N, 84°W, datum: WGS84) were examined from the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California.

An incision was made on the lower portion of the abdomen and one gonad was removed. Histological slides were prepared using conventional methods (Presnell and Schriebman 1997. Humason's Animal Tissue Techniques. Johns Hopkins University Press, Baltimore, Maryland. 572 pp.). One clutch of oviductal eggs was counted. Slides are deposited in LACM.

All five males were undergoing spermiogenesis = sperm formation: January (N = 2), March (N = 1), July (N = 1), August (N = 1). One female from June (LACM 148114, SVL = 75 mm) contained five oviductal eggs. One female each from February and July had quiescent ovaries (no yolk deposition). Presumed neonates were collected in spring: March (N = 1), April (N = 1), May (N = 1), June (N = 2).

The presence of males undergoing spermiogenesis in widely separated months suggests *D. bilobatus* has an extended period of spermiogenesis. Continuous spermiogenesis has been reported for other lizards from Costa Rica (Smith 1968. Biol. Bull. 134:325–331; Goldberg 2008a. Bull. Maryland Herpetol. Soc. 44:42–45; 2008b. Bull. Chicago Herpetol. Soc. 43:130–131). Five eggs is a new minimum clutch size for *D. bilobatus*.

I thank Christine Thacker (LACM) for permission to examine *D. bilobatus* which are part of the CRE (Costa Rica Expeditions) collection donated to LACM by Jay M. Savage in 1998.

Submitted by **STEPHEN R. GOLDBERG,** Whittier College, Department of Biology, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

GONATODES HUMERALIS (NCN). **DEFENSIVE BEHAVIOR.** Curling the tail over the back is a defensive strategy some lizards use to reduce predation (Pianka and Vitt 2003. Lizards: Windows to the Evolution of Diversity. Univ. California Press, Berkeley, California. 333 pp.). By performing this behavior, a lizard may mimic a scorpion and/or expose its tail to predators (diverting attention from more vulnerable areas) (Pianka and Vitt, *op. cit.*). Among Brazilian geckos, this behavior is reported only for *Gymnodactylus carvalhoi* (= *G. geckoides amarali*) (Colli et al. 2003. J. Herpetol. 37:694–706), and *Coleodactylus brachystoma* (Brandão and Motta. 2005. Phyllomedusa 4:139–145), both from the Cerrado biome. Here, we report an observation of similar behavior in the gecko *Gonatodes humeralis*.

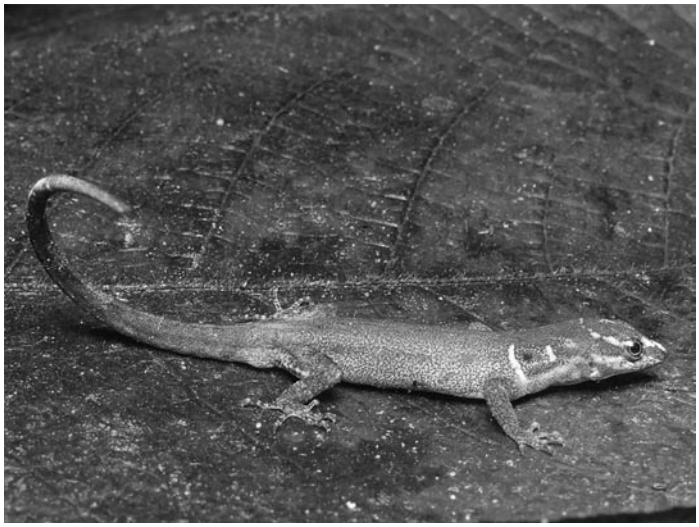

FIG. 1. *Gonatodes humeralis* exhibiting its defensive tail display. Photo by D. J. Santana.

At ca 2000 h On 6 March 2008 during fieldwork in Aripuanã, Estado do Mato Grosso, Brazil, VASP and DJS collected an adult male *G. humeralis* (35.85 mm SVL) sitting on the leaf of a small tree ca. 1.0 m above the ground at the edge of an altered submontane tropical rainforest near human settlement (10.1650°S; 59.4392°W; datum: WGS84; elev. 176 m). The following day, while being photographed, the gecko exhibited a display in which its tail was lifted and held still (Fig. 1), a defensive behavior reported for the first time in this species. This behavior may have one or both of the following causes: 1) Scorpion mimicry (Pianka and Vitt, *op. cit.*), considering that scorpions are common in the study area; and/or 2) Tail exposure as geckos possess particularly fragile tails that detach easily (Pianka and Vitt, *op. cit.*; Brandão and Motta, *op. cit.*).

The collected *G. humeralis* (MZUFV 647) was deposited in the herpetological collection of Museu de Zoologia "João Moojen," Universidade Federal de Viçosa, in Viçosa, Minas Gerais. We thank Energética Águas da Pedra S.A. for financial support; IBAMA for collection permits (029/2006-COFAN and 50/2007-SUPES/MT, process number 02001.003069/2004-42; Permanent License for Collecting Zoological Material (10504-1) to Renato N. Feio, IBAMA registration number 491048); J. Dergam and M. Hayes for suggestions on the manuscript.

GONATODES HUMERALIS (NCN). **HABITAT OCCURRENCE; ESCAPE BEHAVIOR.** *Gonatodes humeralis*, a broadly

distributed gekkonid lizard, occurs from gallery forests of rivers in Brazilian Cerrado across the entire Amazon and Orinoco Basins, east to foothills of the Andes and north to Panamá (Pianka and Vitt 2003. Windows to the Evolution of Diversity. Univ. California Press, Berkeley, California. 346 pp.). In Amazonian Brazil, *G. humeralis* is among the most common lizards, occurring in all kinds of forest, such as terra firme, várzea or igapó, primary or secondary, gallery forests, and patches of forest in savanna areas (Ávila-Pires 1995. Zool. Verhandel. 299:1–706). Here, we report a previously unrecognized pattern of habitat use in *G. humeralis* and an escape behavior not previously mentioned in the literature.

During fieldwork in a mangrove forest, we found two individuals of *G. humeralis* (a male 33.5 mm SVL; a female 23.3 mm SVL). This mangrove forest is basically comprised of *Avicennia germinans*, *Rhizophora mangle*, and *Laguncularia racemosa*, and is flooded by daily tides, resulting in high water salinities (41) during the dry season. This mangrove area is located on the Ajuruteua Peninsula, in the municipality of Bragança, State of Pará, Brazil, and is 6 km from the terra firme to the north and ca. 30 km from the mainland to the south. To our knowledge, *G. humeralis* has not been reported as a part of the typical mangrove fauna. Insects represent a major food source for predators in mangroves (Hogarth 1999. The Biology of Mangroves. Oxford University Press Inc., New York. 240 pp.), and we found insects in the stomachs of both lizards, including gryllids (Orthoptera), chalcidid wasps (Hymenoptera), termites (Isoptera), and nematocerid and pharid flies (Diptera). A number of microhabitats available on the ground in non-flooded tropical forests, such as decayed logs, dead leaves, spaces among roots or else stones, tunnels of termite nests or even axils of terrestrial bromeliads are unavailable to *G. humeralis* for foraging, nesting, or refuge in flooded mangrove areas (Ávila-Pires, *op. cit.*; Maciel et al. 2005. Herpetol. Rev. 36:178). During capture, the *G. humeralis* attempted to escape running around the tree trunk, a characteristic behavior for this species (Ávila-Pires, *op. cit.*). Some attempts at capture resulted in their diving into the brackish mangrove water and submerging 10–15 cm, an escape behavior not previously reported. Study of *G. humeralis* in mangrove forests is needed to clarify how this species copes with this inhospitable environment.

LEPOSOMA PERCARINATUM (NCN). **AQUATIC HABITAT USE**. Lizards of the genus *Leposoma* are conspicuous members of leaf litter herpetofauna in Neotropical forests (Pellegrino et al. 1999. Hereditas 13:15–21; Rodrigues 1997. Herpetologica 53:383–389). The *Leposoma parietale* species group, which occurs from Amazonia to Costa Rica (Rodrigues and Borges 1997. Herpetologica 53:1–6; Uzzell and Barry 1971. Postilla 154:1–39), currently contains 10 species (Rodrigues and Avila-Pires 2005. J. Herpetol. 39:541–546). One, *L. percarinatum*, is parthenogenetic (Pellegrino et al., *op. cit.*; Uzzell and Barry, *op. cit.*) and is probably the most widespread species of *Leposoma* in the Amazon (Avila Pires 1995. Zool. Ver. 299:1–706). The species has been reported to occur either close to the water (near creeks or in várzea and igapó forests) or in terra firme forest (Avila-Pires, *op. cit.*; Crump 1971. Occ. Pap. Mus. Nat. Hist. Univ. Kansas 3:1–62; Martins 1991. Stud. Neo. Fauna Env. 26:179–190; pers. obs.), but aquatic habitat use is unreported. Here, we report an instance of aquatic habitat use.

At 2015 h (at night) on 3 July 2008, SMS observed an adult of *L. percarinatum* active in a pool associated with a small forest creek in a forest fragment near Candeias do Jamari (09.7792°S, 063.6696°W, datum SAD69; elev. 87 m), state of Rondônia, Brazil. The animal was moving at the water surface through floating algae and dead leaves ca. 0.5 m from the edge of the pool. The animal was not collected as it escaped after two capture attempts in the water. Identification was only possible due to the previous experience of the senior author with *Leposoma* in the field (Souza 2007. MSc thesis, Instituto Nacional de Pesquisas da Amazônia, Manaus, Amazonas, Brazil. 73 pp.). This is the first report of *L. pericarinatum* using aquatic habitat.

This observation reinforces the idea of relationship between *L. percarinatum* and *L. ferreirai*, hypothesized as closely related (Rodrigues and Avila-Pires, *op. cit.*). *Leposoma ferreirai*, the only *Leposoma* with a clearly aquatic habit, is restricted to Arquipélago das Anavilhanas, a fluvial archipelago of more than 400 islands that are inundated several months annually by the Rio Negro and is ca. 750 km from Candeias do Jamari.

We thank Prominer Projetos S/C LTDA and Therys Midori Sato for field assistance and IdeaWild for equipment.

LIOLAEMUS AUSTROMENDOCINUS (NCN). **SAUROPHAGY**. *Liolaemus austromendocinus* is a medium-sized liolaemid lizard found in northwestern Patagonia from the Andean mountains of Departamento San Carlos, Mendoza Province (34.00°S latitude) to rocky outcrops of the Añelo Basin, Departamento Añelo, northern Neuquén Province (38.50°S latitude). Dietary data are sparse, but the species is reported to feed on insects (Cei 1986. Reptiles del Centro, Centro-Oeste y Sur de la Argentina. Monogr. IV, Mus. Reg. Sci. Nat. Torino, Italy. 527 pp.). Here we report an observation of interspecific saurophagy by an adult *L. austromendocinus* on an adult *L. bibronii*.

On 7 February 2008 during a field trip to Auca Mahuida volcano (37.6932ºS, 68.8241ºW; datum WGS84; elev. 1348 m, Departamento Añelo, Neuquén Province, northwestern Patagonia, Argentina), we observed an adult *L. austromendocinus* (86.9 mm SVL, 228.9 mm tail) basking on a rock in shrub-steppe habitat. When we

chased it, the lizard ran under a rock where we captured it by hand. One hour after we had temporarily placed this lizard in a plastic container, it regurgitated the remains of a female *L. bibronii* (35 mm long × 10 mm wide). We estimated the original size of the *L. bibronii* by comparison with other preserved *L. bibronii* to be ca. 50 mm SVL. These two lizard species are synoptic in this area of Patagonian steppe and usually share similar habitats. Saurophagy has not been previously documented for *L. austromendocinus*.

Nicolas Frutos verified the identifications and the *L. austromendocinus* (LJAMM 10340) and the *L. bibronii* (LJAMM 10483) were deposited in the Herpetological Collection LJAMM (Luciano Javier Avila Mariana Morando) of the Centro Nacional Patagónico (CENPAT), Puerto Madryn, Chubut.

Submitted by **CRISTIAN HERNAN FULVIO PÉREZ** CENPAT-CONICET, Boulevard Almirante Brown 2825, U9120ACF, Puerto Madryn, Chubut, Argentina (e-mail: liolaemu@criba.edu.ar); **DANIEL ROBERTO PÉREZ**, Universidad Nacional del Comahue, Escuela Superior de Enfermería y Medio Ambiente, Neuquén, Argentina (e-mail: ddeneuquen@yahoo.com); and **LUCIANO JAVIER AVILA**, CENPAT-CONICET, Boulevard Almirante Brown 2825, U9120ACF, Puerto Madryn, Chubut, Argentina (e-mail: avila@cenpat.edu.ar).

LIOLAEMUS BAGUALI (NCN). **SPINAL INJURY.** *Liolaemus baguali* is an uncommon liolaemid lizard endemic to Patagonian steppe environments of western Santa Cruz Province, southern Patagonian, Argentina. During field work on 17 January 2008, along the margins of Ruta Nacional (National Highway) 40, 72.8 km N of its junction Ruta Provincial (Provincial Highway) 288 (49.1040°S, 71.1985°W; datum WGS84; elev. 525 m), Rio Chico Department, Santa Cruz Province, we collected an adult male *L. baguali* (66.4 mm SVL) that appeared to exhibit a scoliosis as had been recently reported for another Patagonian lizard (Frutos et al. 2006. Herpetol. Rev. 37:468–469). After we x-rayed the lizard, we realized that the supposed scoliosis was in fact severe spinal trauma (Fig. 1). The radiograph revealed vertebral displacement and an apparent disconnection between bones. Apparently, the injury had not yet affected the nervous system because the lizard was able to move and run normally. Externally, no evidence of a wound was visible: scales and scale rows were complete and no scars were noticeable. Only a humpback appearance with slight displacement to the right side was evident. Absence of external evidence of injury likely means that it cannot be attributed to a predator. The lizard was found in the west edge of an unpaved road between small to medium rounded rocks periodically disturbed by grazers. The injury may be attributable to crushing between rocks during disturbance by grazers or vehicular traffic. Our observation reveals an unusual ability to survive severe internal injury.

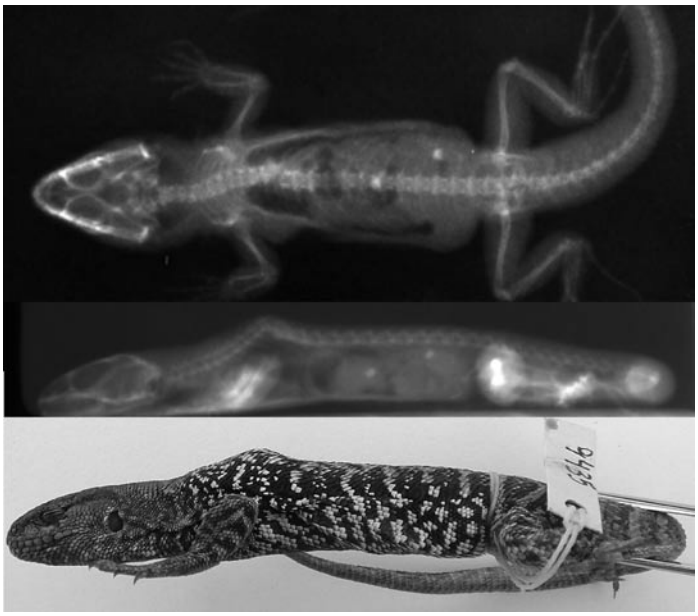

FIG. 1. Top and middle panels: Dorsal and lateral radiographs of the injured *Liolaemus baguali*, arrow indicates the spinal injury. Lower panel: External view, no injury is visible in the dorsal scales.

The lizard was deposited in collection Luciano Javier Avila Mariana Morando (LJAMM) now housed in CENPAT-CONICET (LJAMM 9435).

Submitted by **NATALIA FELTRIN**, **CRISTIAN HERNAN FULVIO PEREZ**, **MARIA FLORENCIA BREITMAN**, and **LUCIANO JAVIER AVILA**, CENPAT-CONICET, Boulevard Almirante Brown 2825, U9120ACF, Puerto Madryn (Chubut), Argentina (e-mail: avila@cenpat.edu.ar).

MICROACONTIAS LITORALIS (Coastal Legless Skink). **COPULATION.** Few ecological and natural history data exist for many fossorial herpetofaunal species, including the skink *Microacontias litoralis*. During the late afternoon of 25 October 2007, a pair of *M. litoralis* was discovered in the process of copulating in white sand dunes near Noup, on the Namaqualand Coast, Northern Cape, South Africa (30.10832°S; 17.21752°E; datum WGS84; elev. 43 m). The lizards were partly exposed in the sand with less than 50% of their bodies obscured from view. Their bodies were entwined, crossing over each other in three places. Temperature of the sand was 28.3ºC; air temperature was 22.2ºC. On closer inspection, the lizards attempted to escape but were captured. The male's hemipenes were exposed. The male measured 108 mm SVL (26 mm tail, 1.4 g) and showed orange and brown coloration as described by Branch (1998. Field Guide to the Snakes and Other Reptiles of Southern Africa. Struik Publishers, Cape Town, South Africa. 399 pp.). The female measured 111 mm SVL (30 mm tail, 1.4 g) and was an overall orange color with some fine dark speckling over the entire dorsum. These data represent the first on copulation for this species. Both specimens were killed, preserved, and deposited at Bayworld (Port Elizabeth Museum: PEM R17456–57).

Submitted by **BRYAN MARITZ**, School of Animal, Plant and Environmental Sciences, University of the Witwatersrand, P.O. Wits, Johannesburg, 2050, South Africa, e-mail: maritz@gecko.wits.ac.za.

OPHISAURUS COMPRESSUS (Island Glass Lizard). **PREDATION**. Known predators of glass lizards (*Ophisaurus* spp.) include colubrid, elapid, and viperid snakes (e.g., Schmidt 1932. Copeia 1932:6–9; Palis 1993. Herpetol. Rev. 24:59, 62; Palmer and Braswell 1995. Reptiles of North Carolina. Univ. North Carolina

Press, Chapel Hill, North Carolina. 412 pp.; Himes 2004. Herpetol. Rev. 35:123–128), several species of birds (Fitch and Bare 1978. Trans. Kansas Acad. Sci. 81:1–13; Fogarty and Hetrick 1973. Auk 90:268–280; Moore et al. 2005. Herpetol. Rev. 36:182), and armadillos and raccoons (Stains 1956. Misc. Publ. Mus. Nat. Hist. Univ. Kansas 10:1–76; Wirtz 1985. *In* G. G. Montgomery [ed.], The Evolution and Ecology of Armadillos, Sloths, and Vermilinguas, pp. 439–451. Smithsonian Inst. Press, Washington, DC). Predators of *O. compressus* have been suspected but not documented (Moler 2008. *In* J. Jensen et al. [eds.], Amphibians and Reptiles of Georgia, pp. 283–284. Univ. Georgia Press, Athens, Georgia).

CR found skeletal remains of an adult *O. compressus* (FMNH 153660) in Bobcat (*Lynx rufus*) scat collected on 23 November 1997 on the north end of Cumberland Island, Camden County, Georgia (30.9292°N, 81.4097°W; NAD27; elev. 3 m). Following elimination of feral cattle, the area has been in a transitional phase between open savannah-like interdune habitat and a more forested community. Bobcats were the only large, roaming predators on the island at the time. The scat also included remains of a young raccoon and a small, unidentified bird. Preferred prey of Bobcats that occur on the island are Marsh Rabbits (*Sylvilagus palustris*) and Cotton Rats (*Sigmodon hispidus*) (Whitaker and Hamilton 1998. Mammals of the Eastern United States, Cornell Univ. Press, Ithaca, New York. 583 pp.). However, they are also known to kill and eat several species of snakes (e.g., Fritts and Sealander 1978. J. Wildl. Manage. 42:533–539; King et al. 1983. Brimleyana 9:111–122) and at least two species of lizards, *Sceloporus poinsetti* and *Phrynosoma* sp. (Young 1958. The Bobcat of North America, Stackpole Books, Harrisburg, Pennsylvania. 193 pp.; Delibes and Hiraldo 1987. Southwest. Nat. 32:457–461). Previous records of Bobcat prey on Cumberland Island include seven species of mammals and one unidentified bird but no reptiles (Baker et al. 2001. Amer. Midl. Nat. 145:80–93). Our observation is the first report of a mammalian predator of *O. compressus* and a third prey lizard species for the bobcat.

We thank John Jensen, Andy Price, and Laurie Vitt for help with literature and Kenny Krysko for allowing us to examine glass lizard skeletons in the Florida Museum of Natural History herpetology collection.

Box 796, St. Marys, Georgia 31558, USA (e-mail: cimuseum@yahoo.com); and **PETER A. MEYLAN**, Department of Natural Sciences, Eckerd College, St. Petersburg, Florida 33711 USA (e-mail: meylanpa@eckerd.edu).

PHYLLODACTYLUS HOMOLEPIDURUS (Sonoran Leaf-toed Gecko). **ENDOPARASITES.** Endoparasitic helminths from *Phyllodactylus homolepidurus,* which is known from western Sonora, México and the Isla San Pedro Nolasco (Grismer 2002. Amphibians and Reptiles of Baja California, including its Pacific Islands and the Islands in the Sea of Cortés. Univ. California Press, Berkeley. 399 pp.), are unreported. Hence we present the first information on its helminths.

Five *P. homolepidurus* (4 females, 1 male, mean SVL = 60.0 mm ± 4.6 SD, range 54–66 mm) obtained from the herpetological collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California, USA were examined for helminths. Lizards were from Isla San Pedro Nolasco (27.96667°N, 111.38333°W, datum WGS84; elev. 152 m; LACM 25086, collected 1964) or the vicinity of Hermosillo, Sonora, México (29.06667°N, 110.96667°W, datum WGS84; elev. 210 m; LACM 37565, 93784, 93785, collected 1967; 122509, collected 1975). The lizards were opened by a mid-ventral incision and the gastrointestinal tract removed and opened. The esophagus, stomach, small and large intestines and body cavity were searched for endoparasites using a dissecting microscope. One species of Nematoda was found in the large intestines of LACM 25086, 37565, 93785 and 122509 (mean number of helminths = 18.0 ± 15.9 SD, range = 1–36). They were cleared in a drop of glycerol, cover-slipped, studied as wet mounts and identified as *Spauligodon oxkutzcabiensis*. Voucher nematodes were deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland as USNPC (100789). *Spauligodon oxkutzcabiensis* was initially described as *Pharyngodon oxkutzcabiensis* from the gecko *Thecadactylus rapicaudus* taken in the Yucatan (Chitwood 1938. Publ. Carnegie Inst. Wash. 491:51–66). Skrjabin et al. 1960 (Oxyurata of Animals and Man, Part 1. Israel Program of Scientific Translation, Jerusalem. 526 pp.) relocated it to its current genus. *Spauligodon oxkutzabiensis* has previously been reported in *Phyllodactylus reissii* from Peru (Goldberg and Bursey 2004. Herpetol. Rev. 35:395), *Sceloporus malachiticus* from Costa Rica (Goldberg and Bursey 1992. J. Helminthol. Soc. Wash. 59:125–126), *Tropidurus guarani* from Paraguay (Goldberg and Bursey 2004. Comp. Parasitol. 71:203–207) and *Sceloporus formosus, S. grammicus, S. megalepidurus, S. mucronatus* and *S. torquatus* from Distrito Federal, Hidalgo, Oaxaca, Puebla and Querétaro, México (Goldberg et al. 2003. Southwest. Nat. 48:208–217). *Phyllodactylus homolepidurus* is the third species of gecko reported to harbor *S. oxkutzcabiensis*. Sonora, Mexico is a new locality record.

We thank T. Doleck (Whittier College) for assistance with dissections and C. Thacker (LACM) for permission to examine specimens.

Submitted by **STEPHEN R. GOLDBERG,** Whittier College, Department of Biology, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu) and **CHARLES R. BURSEY,** Pennsylvania State University, Department of Biology, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

PODARCIS HISPANICA **COMPLEX** (North African Wall Lizard). **ARBOREAL BEHAVIOR.** Lacertids of the genus *Podarcis* surround the Mediterranean Basin, where they inhabit a broad range of habitats, including coastal dunes, open grassy areas, human-developed environments, Mediterranean maquís and mountain forests (Arnold 1987. J. Zool. (B) 1:739–782). In these habitats, *Podarcis* utilize diverse microhabitats, such as stony walls and rocky surfaces, ruins, scrub, paths and road sides, bushes and numerous anthropogenic structures (Arnold and Ovenden 2002. A field guide to the reptiles and amphibians of Britain and Europe. Harper-Collins. London, United Kingdom. 272 pp). Members of the *Podarcis hispanica* species complex (hereafter *P. hispanica**), a group whose systematics remains unresolved (Harris and Sá-Sousa.

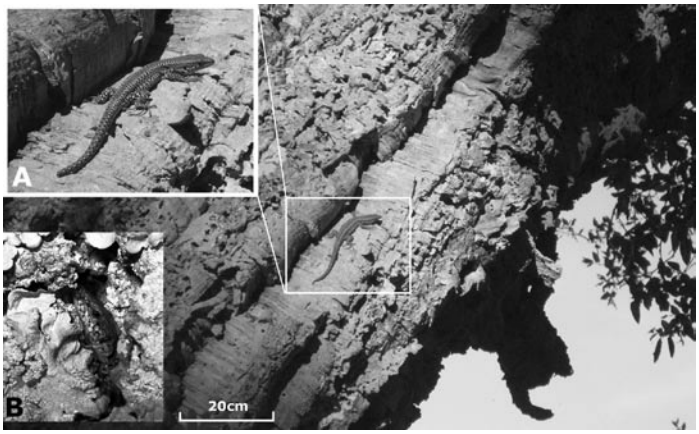

FIG. 1. North African Wall Lizard, *Podarcis hispanica**, A) basking on a Cork Oak (*Quercus suber*), and B) using its surface as a refuge in Cape Negro, Tunisia.

2002. Mol. Phylogenet. Evol. 23:75–81), have been characterized as principally saxicolous, climbing on rocks, walls, parapets and other anthropogenic structures, at least in the Iberian Peninsula, which represents the center of its geographic distribution (Arnold and Ovenden, *op. cit.*). Hence, here we report on the arboreal habit of *Podarcis hispanica** from Tunisia.

During a field-trip to northern Tunisia in May 2008, we repeatedly observed *P. hispanica** climbing on tree trunks, either spontaneously in order to bask and feed or in response to our presence, presumably to seek refuge (Fig. 1). We recorded this behavior at all sites where we encountered *P. hispanica**, including El Feidja National Park (36.5045°N, 8.3137°E, datum: WGS84), the vicinity of Ain Draham (36.7227°N, 8.6775°E) and Cap Negro (37.0685°N, 9.0465°E). *Podarcis hispanica** used primarily Cork Oaks (*Quercus suber*), but European Chestnuts (*Castanea sativa*) were also used. Both adult males and females displayed this behavior, but we never observed subadults on trees. When adults fled to the trees, the lizards first climbed to roughly one meter in height, then progressively further up if they continued to feel threatened, reaching heights up to 8 m above the ground. When directly approached by one of us, they used complex tree surfaces as refuge, hiding in holes beneath the bark (Fig. 1). Additionally, after releasing two non-resident lizards on a cork oak, we observed agonistic behavior toward these individuals by resident lizards. This implies use of trees that may encompass part of individual territories and refuge sites.

Though scattered observations exist of at least three *Podarcis* utilizing trees (i.e., *P. hispanica*, *P. muralis* and *P. sicula*; Arnold and Ovenden, *op. cit.*), this is the first report of extensive arboreality in the genus. Other members of the *P. hispanica* species complex (*sensu* Harris and Sá-Sousa, *op. cit.*) have been observed to use downed trees as shelter or to climb palm trees in human-developed habitats (pers. obs.). However, use of trees by *P. hispanica** in the Iberian Peninsula has been exclusively mentioned as incidental (Barbadillo et al. 1999. Anfibios y Reptiles de la Península Ibérica, Baleares y Canarias. Editorial GeoPlaneta. Barcelona, Spain. 419 pp.; Pérez-Mellado 1998. *In* Salvador [coord.], Fauna Ibérica, vol. 10, Reptiles, pp. 258–272. Museo Nacional de Ciencias Naturales, CSIC. Madrid, Spain) and we have never observed its regular use of trees in the Iberian Peninsula, even though oaks and other large trees are often available. In contrast, we found arboreal behavior frequent in Tunisian *P. hispanica**. This may reflect available habitat within the range of wall lizards in Tunisia, where they are confined to the northwestern part of the country, and correspond to the distribution of dense, humid Mediterranean forests (Kaliontzopoulou et al. Can. J. Zool., *in press*). In such closed habitats, stony and rocky which provide potential terrestrial refuges, are infrequent and terrestrial basking opportunities are very limited. Consequently, lizards may take advantage of the higher branches of big trees in order to find light and thermoregulate, and use the bark of trunks as a refuge. Similar behavior has also been incidentally observed in *P. hispanica** in Algeria (MAC, JCB, pers. obs.), but not in *P. vaucheri* in Morocco, even though long-term studies have been carried out on this recently recognized species (Busack et al. 2005. Amphibia-Reptilia 26: 239–256).

PRISTIDACTYLUS SCAPULATUS (NCN). **SAUROPHAGY**. *Pristidactylus scapulatus* inhabits the eastern slope of the Andean Cordillera from north of San Juan in San Guillermo Provincial Reserve to Chubut Province (Cei 1986. Museo Regionale di Scienze Naturali Torino. Monografie IV. Torino, Italia. 527 pp.). Its diet includes scarab (Scarabaeidae), darkling beetles (Tenebrionidae), and fruits of *Lycium chanar* and *Ephedra breana* (Acosta et al. 2004. Herpetol. Rev. 35:171–172), but saurophagy is unreported. Hence, here we report an observation of interspecific saurophagy by an adult *P. scapulatus* on a juvenile *Phymaturus punae*.

On 5 December 2004 during the course of Project "Estudio de Línea de Base San Guillermo" in the Parque Nacional San Guillermo, Departamento Iglesia, Provincia de San Juan (29.25°S, 69.48°W; datum: WGS84; elev. 3400 m), we collected an adult female *P. scapulatus* (98 mm SVL) by hand. Its stomach contents were examined and found to contain a juvenile of *Phymaturus punae* (51 mm SVL). The *P. scapulatus* female was gravid with three eggs in the oviduct.

Saurophagy has been documented in other *Pristidactylus* (e.g., *P. nigroiugulus* preying on juvenile *Liolaemus fitzingerii* and *L. boulengeri*; Cei et al. 2004. Boll. Mus. Reg. Sci. Nat. Torino 21:159–192). *Pristidactylus scapulatus* and *P. punae* are both common in Parque Nacional San Guillermo and both use similar

microhabitats. Juvenile *P. punae* may represent important prey for gravid female *P. scapulatus*.

The female *P. scapulatus* (IMCN-UNSJ4303) and its *P. punae* prey (IMCN-UNSJ4304) were deposited in the collection of the Facultad de Ciencias Exactas, Físicas y Naturales, Universidad Nacional de San Juan

SCELOPORUS JARROVII (Yarrow's Spiny Lizard). **AQUATIC ESCAPE BEHAVIOR**. Use of aquatic habitats to evade predators is well documented in terrestrial lizards (Bauer and Jackman 2008. Hydrobiologia 595:581–586; Daniels and Heatwole 1990. Mem. Queensland Mus. 29:374–387; Greene 1988. *In* Gans and Huey [eds.], Biology of Reptilia, Volume 16, pp. 136–143, Alan R. Liss, New York, New York). However, this behavior is not reported for *Sceloporus jarrovii*. Here, we report four observations of three adult *S. jarrovii* entering water to escape.

All observations were made in the Peloncillo Mountains, Hidalgo Co., New Mexico, USA (109.017°W, 31.483°N, WGS84; elev. 1726 m) at an artificial impoundment formed by a reinforced concrete dam (13–15 m × 2 m) built into a canyon streambed. On 3 September 2007, water depth of the impoundment was < 0.5 m and the exposed surface area of the dam wall was ca. 19–23 m^2. On 6–7 September 2007, heavy monsoon rains increased the impoundment water depth to 2 m and decreased the exposed surface area of the dam wall to ca. 2 m^2, with water reaching 13 cm from the top of the dam.

On 11 September 2007, we observed an adult *S. jarrovii* perched on top of the dam. KJL unsuccessfully attempted to capture the lizard by hand. Suspecting that he had knocked the lizard into the water, we searched the flooded terrestrial vegetation and water adjacent to the dam, but only caught sight of a sinking detached tail. While searching, BDS observed the tailless lizard perched vertically on the dam 15–20 cm below the water surface, where we photographed it from above. After ca. 2 min, KJL attempted to nudge the lizard. The lizard ran ca. 1–2 m along the wall underwater, then exited the water and retreated into a pile of debris at the end of the dam. In the following days, during separate episodes, we observed similar behavior by the same lizard (recognized by its lost tail), and another adult that remained submerged for 80 sec and 20 sec, respectively. The lizards appeared to have no difficulty entering the water and running along the dam wall while submerged. We also observed a third adult leap from the dam and swim ca. 1.5 m to an adjacent willow tree (*Salix* spp.). Unfortunately, we were unable to sex any of the lizards involved in aquatic escape behaviors.

This represents the first report of *S. jarrovii* utilizing an aquatic habitat in any context. Aquatic escape behavior is rare among sceloporine lizards, but *S. spinosus floridanus* uses the aquatic environment for escape as a last resort (Strecker 1928. Contr. Baylor Univ. Mus. 15:3–9). In the Peloncillo Mountains, aquatic escape behavior seems odd given the dearth of standing water. However, populations faced with intense predation pressure are predicted to evolve more diverse escape tactics (Schall and Pianka 1980. Am. Nat. 115:551–566). In the nearby Chiricahua Mountains at a similar elevation (1675 m), *S. jarrovii* have several potential predators and cope with high predation pressure (Ballinger 1979. Ecology 60:901–909). Stomach content analyses from the region indicate that *S. jarrovii* compose 45% of prey taken by banded rock-rattlesnakes (*Crotalus l. klauberi*; Holycross et al. 2006. J. Herpetol. 36:589–597). Considering the geographic similarities of these studies, *S. jarrovii* may encounter high predation pressure in the Peloncillo Mountains. Hence, aquatic escape may be an occasionally used escape tactic with important anti-predator benefits.

We thank the Joe Jackson College of Graduate Studies & Research at the University of Central Oklahoma for financial support, Paul A. Stone and Troy A. Baird for insightful reviews, and Charles W. Painter for encouraging words of wisdom.

SCELOPORUS PYROCEPHALUS (Mexican Boulder Spiny Lizard). **DIET**. *Sceloporus pyrocephalus*, a phrynosomatid lizard endemic to México, occurs in tropical dry forest in coastal areas of the states of Jalisco, Colima, Michoacán and Guerrero, including the lowlands of the Río Balsas Basin (Smith and Taylor 1950. U.S. Nat. Mus. Bull. 199:1–253). Information on its biology is sparse. Here we report the first data on its diet.

The study was conducted at Rancho Las Bermejas (18.5833°N, 101.2136°W; datum WGS84; elev. 215 m) ca. 30 km W of the town of Huetamo and 6 km N of the Río Balsas, Michoacán, México. Vegetation consists of tropical dry forest. Lizards were caught opportunistically. Fourteen animals were collected during the wet season (July) and 7 during the dry season (November) of 2000. Individuals were assigned to two age classes (adults ≥ 45 mm SVL; juveniles < 45 mm SVL, Ramirez-Bautista and Olvera-Becerril 2004. J. Herpetol. 38:225–231). Lizards were frozen to arrest digestion, and stomachs were dissected to evaluate their contents. Food items were preserved in 70% ethanol and identified to the lowest possible taxonomic level. We calculated the relative abundance of food items by volume (%V), and their frequency among stomachs examined (%F). Estimates of dietary diversity and overlap were based on %V. We calculated the Shannon-Wiener Index (H') to estimate dietary diversity. Dietary diversity values were compared using Hutcheson's t-test. We used the percent overlap index of Schoener (1970. Ecology 51:408–418) to describe seasonal and ontogenetic changes in diet.

We found 28 different terrestrial arthropod taxa in the 21 lizard stomach samples (Table 1). Five groups were dominant: flies (Diptera), true bugs (Hemiptera), beetles (Coleoptera), and wolf spiders (Lycosidae) collectively constituted more than 70% of the diet by volume, and ants (Formicidae) were the most frequent prey items (95% of the stomachs). Dietary diversity (H') for the entire sample was 2.37. Eleven prey taxa recorded during wet season were not recorded during the dry season, whereas 6 groups present during dry season were absent during the wet season (Table

TABLE 1. Stomach contents of *Sceloporus pyrocephalus* in wet and dry season. Variation in prey taxa is described as the percentage of stomachs in which the taxon was found (%F), and percentage of stomach volume (in mm^3) represented by that taxon (%V).

1). Inter-seasonal dietary overlap was 41.5% and dietary diversity was significantly greater in wet (H' = 2.11) versus dry (H' = 1.89) seasons ($t = 2.24$, $df = 37$, $P < 0.05$). During the dry season, the most important prey were true bugs and beetles, whereas dipterans and wolf spiders dominated wet-season diet (Table 1). During the dry season, we found ants in all the stomachs, whereas during wet season, beetles were present in all the stomachs. The reduction in the dietary diversity index during dry season suggests that prey abundance and availability of arthropods declines during that season.

We found a moderate level of dietary overlap (39.5 %) between juvenile and adult lizards, and dietary diversity differed between juvenile (H' = 2.21) and adult (H' = 1.77) lizards ($t = 4.60$, $df = 33$, $P < 0.05$). For juveniles the most important prey (by volume) were true bugs (21%), beetles (19%) and ants (17%), whereas wolf spiders (26%), true bugs (22%) and dipterans (24%) dominated adult diet. Based on frequency of occurrence, ants dominated the diet of both adult (100%) and juvenile lizards (94%).

Relatively high dietary diversity and the fact that no prey taxon contributed more than 25% by volume to the diet may indicate either that *S. pyrocephalus* is a dietary generalist or that high variability exists among individuals in their dietary preferences. Considering the markedly seasonal environment in which this species is found, an opportunistic diet may be an advantageous foraging strategy for coping with temporal fluctuations in prey diversity, levels of activity, and availability, as predicted by optimal foraging theory (Pianka and Vitt 2003. Lizards: Windows to the Evolution of Diversity. Univ. of California Press, Berkeley, California. 333 pp.).

We thank P. Suazo Pineda, owner of Rancho Las Bermejas for making all facilities available during this study and the Consejo de Investigación Científica, UMSNH project 5.5 for financial assistance. We thank M. Hayes for his constructive comments.

SCELOPORUS UNDULATUS (Eastern Fence Lizard). **DEFLECTION DISPLAY.** Many squamate species attempt to deflect predation attacks toward their tails. For instance, Ringneck Snakes coil their tails to show the bright underside in an apparent deflection display (McCallum et al. 2006. Herpetol. Nat. Hist. 10:91–94). Better known are display tactics among lizards with autotomous tails. Broad-headed Skinks may undulate their tail just prior to fleeing (Cooper 1998. Behav. Ecol. 9:598–604; Cooper 1998. Can. J. Zool. 76:1507–1510). Some geckos may also display their tail to distract predators away from the head or body (Congdon et al. 1974. Science 184:1379–1380). These displays are intended to improve chances of escape. Here, we provide an observation of such a deflection display in *Sceloporus undulatus*.

At ca. 1530 h on 18 March 2004, JWS noticed an adult female *S. undulatus* on a split-face concrete block building at a private residence in Chester County, Tennessee, USA (35.47576°N, 88.56750°W; datum WGS84; elev. 165 m). The lizard was chased for 2–3 min until cornered. At that point, it remained still except that it began undulating its entire tail at a frequency of ca. 1 undulation every 1–2 sec. It did not try to flee but remained motionless even as it was picked up. When released, the lizard still did not try to escape; rather, it began undulating its tail once more. As JWS backed away the undulations would slow down and then would intensify when JWS re-approached. The lizard still did not flee when JWS moved out of its line-of-sight; when JWS returned ca 5 min later, it renewed its tail display while the rest of its body continued to remain motionless. JWS again left for ca. 5 min with parallel results upon return. Only after JWS had been out of sight for > 15 min did the lizard finally leave.

We have never previously witnessed this behavior in *S. undulatus* and are unaware of presumptive deflection displays reported for this species in the scientific literature.

STANLEY**, Department of Biological Science, Arkansas State University, PO Box 599, State University, Arkansas 72467-0599, USA (e-mail: jonathanw.stanley@smail.astate.edu); and **BRIAN P. BUTTERFIELD**, Department of Biology, Freed-Hardeman University, 158 E. Main St., Henderson, Tennessee 38340, USA (e-mail: bbutterfield@fhu.edu).

TROPIDURUS HISPIDUS (NCN). **FROG PREDATION**. As with most *Tropidurus,* the diet of *T. hispidus* is mainly arthropods (e.g., *T. oreadicus* and *T. spinulosus*, Colli et al. 1992. J. Herpetol. 26:66–69; *T. torquatus*, Fialho et al. 2000. J. Herpetol. 34:325–330; *T. montanus*, Van Sluys et al. 2004. J. Herpetol. 38:606–611). Ants, beetles, insect larvae and termites comprise the numerical majority of *T. hispidus* diet in rock outcrops in Brazilian Amazonia (Vitt et al. 1996. J. Trop. Ecol. 12:81–101). Plant material (e.g., leaves, flowers and fruits) is also an important portion of the total volume ingested in different *T. hispidus* populations: one from a caatinga biome (Vitt 1995. Occ. Pap. Oklahoma Mus. Nat. Hist. 1:1–29) and one from "campos rupestres" (rocky meadow) habitats (Van Sluys et al., *op. cit.*). Besides invertebrates and plant material, *T. hispidus* occasionally eat small vertebrates, such as frogs (Vitt et al. 1996, *op. cit.*) and other lizards (Vitt 1995, *op. cit.*). Here, we report a frog previously unreported as prey for *T. hispidus* in a caatinga biome at the Estação Ecológica do Seridó (ESEC Seridó), Serra Negra do Norte municipality, Estado do Rio Grande do Norte, Brazil.

During an ecological study of *Tropidurus* in rocky habitats at ESEC Seridó (06.5767°S, 37.2558°W, datum: WGS84; elev. 192 m) a total of 84 stomachs of *T. hispidus* were analyzed. The stomach contents of an adult female (99 mm SVL) captured on a rock surface on 14 February 2008, included an adult hylid frog *Scinax x-signatus* (30.0 mm in length [SVL], 20.0 mm in width and 6,280 mm^3 in volume).

Based on stomach analysis of 74 *T. hispidus* by Vitt et al. 1996 (*op. cit.*), 11 frogs were found as prey in 6 lizards. The microhylid *Elachistocleis ovalis* was the only anuran identified to species among these frogs. However, in contrast to our observation, all the frogs recorded by Vitt et al. 1996 (*op. cit.*) were juveniles and comprised a relatively small total volume (1,473 mm^3).

The *T. hispidus* (CHBEZ 1994) was deposited in the herpetological collection of Universidade Federal do Rio Grande do Norte, Natal City. We thank the Programa PELD/CNPq - Caatinga: Estrutura e Funcionamento for logistic support, U. Caramaschi for identification of the frog, and M. Hayes for helpful comments on this note. A grant from the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) to L.B. Ribeiro (process 141993/2006-5) supported this study, and IBAMA provided a permit (Permit 206/2006 and Process 02001.004294/03-15).

Submitted by **LEONARDO B. RIBEIRO** (e-mail: ribeiro.lb@gmail.com) and **ELIZA M. X. FREIRE** (e-mail: elizajuju@ufrnet.br), Programa de Pós-Graduação em Psicobiologia, Universidade Federal do Rio Grande do Norte, Centro de Biociências, Departamento de Fisiologia, Caixa Postal 1511; Campus Universitário Lagoa Nova, CEP 59078-970, Natal, Rio Grande do Norte, Brazil.

TROPIDURUS SEMITAENIATUS (NCN). **DRINKING BEHAVIOR**. Many reptiles drink water (Minnich 1982. *In* Biology of the Reptilia, pp. 325–395. Academic Press, New York, New York), and many use behavioral strategies and adaptations in morphology and physiology associated with living in habitats with little water (Minnich 1979. *In* Comparative Physiology of Osmoregulation in Animals, pp. 391–641. Academic Press, London, UK). One such behavior, drinking water, has been recorded relatively infrequently among lizards dwelling in arid habitats (e.g., Meyer 1966. Copeia 1966:126–128; Fusari 1985. Copeia 1985:981–986; Sherbrooke 1993. J. Herpetol. 27:270–275; Sherbrooke 2004. Amphibia-Reptilia 25:29–39). Hence, we describe drinking behavior in the tropidurid lizard *Tropidurus semitaeniatus* for the first time.

Tropidurus semitaeniatus is broadly distributed in the rocky habitats of the semi-arid caatingas of northeastern Brazil (Vanzolini et al. 1980. Répteis das Caatingas. Acad. Bras. de Ciênc., Rio de Janeiro, Brazil. 161 pp.). High temperatures, low humidities, and low, often-irregular precipitation concentrated in 2–3 months of each year characterize these caatingas (Nimer 1972. Rev. Bras. Geog. 34:3–51; Reis 1976. Ann. Acad. Bras. de Ciênc. 48:325–335; Andrade-Lima 1981. Rev. Bras. Bot. 4:149–153).

Our observations were made at a caatinga at the Estação Ecológica do Seridó (Ecological Station of the Seridó [ESEC Seridó]; 6.5767°S, 37.2558°W, datum: WGS84; elev. 192 m), Serra Negra do Norte municipality, Estado do Rio Grande do Norte, Brazil.

At 0810 h and 0930 h, respectively, on 7 and 8 October 2007, LBR observed the drinking behavior in 8 *T. semitaeniatus* to which he experimentally offered water in the course of making focal animal observations of foraging behavior. Water was offered to lizards by dripping it directly on a rock surface (~1 m^2) and on dry leaves at a distance ~1 m from the animals using a 20-ml syringe. Lizards rapidly demonstrated interest in water offered as soon as they located it visually or heard the sound of the drops on dry leaves. During this month of heavy drought, air temperature and humidity at the time of observations on the first day was 33.2ºC and 38.6%, whereas at the time of observations on the second day, air temperature was 32.3ºC and humidity was 36.1%.

To drink the water from warm rock surfaces, each *T. semitaeniatus* kept its forelegs flexed such that its belly did not contact the substrate. With the head oriented down, their snout touched the accumulated water in the rock fissures of the rock (Fig. 1) and based on contractions of the throat, they seemed

FIG. 1. *Tropidurus semitaeniatus* drinking water in the rock fissure of the rock at the Estação Ecológica do Seridó, Brazil.

to swallow it. Where water was in a thin laminar layer on rock surfaces, the lizards tongue-flicked rapidly in an apparent attempt to maximize their intake before the water evaporated from warm surfaces (> 40°C). Lizards also alternating quickly among fissures holding water also seemed to be an attempt to maximize intake. Water offered in dry leaves appeared to allow more time to access than that offered on warm rocks, and water on dry leaves also seemed to be more easily consumed.

Given the scarce precipitation on caatingas, *T. semitaeniatus* are thought to acquire most of their water from animal prey, mainly termites (Vitt 1995. Occ. Pap. Oklahoma Mus. Nat. Hist. 1:1–29), because vegetation becomes completely dry during drought. The drinking behavior we described may be used opportunistically by *T. semitaeniatus* as soon as the annual rains appear in northeastern Brazil.

We thank the Programa PELD/CNPq – Caatinga: Estrutura e Funcionamento for logistic support, and M. Hayes for suggestions on the manuscript. This study was supported by a research grant from the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) to L.B. Ribeiro (process 141993/2006-5), and the permit for the work was given by IBAMA (Permit 206/2006 and Process 02001.004294/03-15).

Submitted by **LEONARDO B. RIBEIRO** (e-mail: ribeiro.lb@gmail.com); and **ELIZA M. X. UTA STANSBURIANA (Side-Blotched Lizard). **NOCTURNAL ACTIVITY; FORAGING BEHAVIOR.** *Uta stansburiana* is a small (up to 6.3 cm SVL) sceloporine lizard common throughout much of the arid western United States (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin, New York, New York. 533 pp.) that is typically associated with mixed fine substrate and rock habitats below elevations of ca. 1,850 m (St. John 2002. Reptiles of the Northwest. Lone Pine, Auburn, Washington, USA. 256 pp.). Its diel activity pattern is typically bi-modal, occurring during the morning (beginning at 0900 h) or early evening (1730–1830 h), and centered around foraging or mate searching behavior (Parker and Pianka 1975. Copeia 1975:615–632). Reports of crepuscular activity exist for *Sceloporus jarrovi* and *S. virgatus* in southeast Arizona (Duncan et al. 2003. Southwest. Nat. 48:218–222), but reports of nocturnal activity among sceloporine lizards are rare. Hence, here I report an observation of nocturnal behavior in *U. stansburiana*.

At 0115 h on 18 May 2008, I observed 3 adult *U. stansburiana* on Huntzinger Road in eastern Kittitas County, Washington (46.86305°N, 119.97155°W, datum: WGS84; elev. ca. 185 m). Two individuals appeared to be basking (via thigmothermy) on the road. Their limbs were splayed out and each had a flattened appearance. A third animal was observed actively pursuing insects on the road ca. 3 m away (the road was illuminated via a full moon). Air temperature at the time of observation was 28°C, and the daytime high in the area, recorded at 1530 h 1.0 m above the surface in the shade, approached 43.5°C. Surrounding habitat was shrub-steppe characteristic of much of central Washington (Daubenmire 1970. Steppe Vegetation of Washington. Washington Agric. Exp. Station Tech. Bull. 62, Pullman, Washington. 131 pp.), dominated by big sagebrush (*Artemesia tridentata*), rabbitbrush (*Chrysothamnus* spp.), various annuals, and in some areas, a few invasive exotics (*Bromus* sp. and *Centaurea* sp.).

I thank M. Hayes for editoral suggestions.

Submitted by **ROBERT E. WEAVER**, School of Biological Sciences, Washington State University, Pullman, Washington, USA; e-mail: weaverr@wsu.edu.

SERPENTES — SNAKES

BOA CONSTRICTOR (Boa Constrictor). **DIET.** *Boa constrictor* is a widely distributed, large-bodied dietary generalist that consumes a wide taxonomic diversity of prey including invertebrates, fish, lizards, birds, and mammals (Quick et al. 2005. J. Herpetol. 39:304–307). Though dietary habits of continental *B. constrictor* are well-documented, less data exist concerning the diet of populations inhabiting neotropical islands. Iguanas of the genus *Ctenosaura* have been documented in the diet of *B. constrictor* inhabiting the Bay Islands of Honduras (Gutsche 2005. Herpetol. Rev. 36:317; Reed et al. 2006. Herpetol. Rev. 37:84) and Green Iguanas (*Iguana iguana*) have been reported in the diets of individuals inhabiting Aruba (Quick et al., *op cit*.). Here we report an additional iguana prey item for *B. constrictor* from the island of Dominica in the Lesser Antilles, West Indies.

On 13 July 2004, MG observed a dead *B. constrictor* (ca. 2 m total length) on the main road passing through Desirade (15.58333°N, 61.31667W°) in Woodford Hill on the northeastern coast of Dominica. An adult female *Iguana delicatissima* (Lesser Antillean Iguana; ca. 27 cm SVL) was protruding through a laceration in the snake's body. Eggs from the iguana were strewn along the road and a broken and a rotten branch of a White Cedar (*Tabebuia pallida*) was discovered next to the specimen. It is assumed that the snake captured and ingested the iguana in the White Cedar and its excessive mass caused the rotten tree limb to break. Another *B. constrictor* (ca. 2 m TL) was discovered by CRK and LP on 24 August 2007 in the Batalie Beach area (15.45027°N, 61.44694°W) located on the west coast of Dominica. The snake was resting on the ground in a shallow cave along a rock wall 12 m from the ocean. A single scat (16 × 3 cm) was discovered 1 m from the snake. The scat contained skeletal elements, crest scales, and six eggs of *I. delicatissima*. These observations augment the list of prey items for *B. constrictor* and suggest that large-bodied iguanas may be more common prey than previously documented.

We thank the Center for Conservation and Research for Endangered Species (CRES) of the Zoological Society of San Diego for support.

Submitted by **CHARLES R. KNAPP**, Conservation and Research of Endangered Species, Zoological Society of San Diego, 15600 San Pasqual Valley Road, Escondido, California 92027, USA (e-mail: cknapp@ufl.edu); **McDONALD GREENAWAY** (e-mail: forestry@cwdom.dm), **ARLINGTON JAMES** (e-mail: arljames@cwdom.dm), Forestry, Wildlife and Parks Division, Botanic Gardens, Roseau, Commonwealth of Dominica, West Indies; and **LYNDON PRINCE**, Salisbury Village, Commonwealth of Dominica, West Indies.

BOTHROPS ASPER (Mapanare, Lancehead). **PREY.** *Bothrops asper* is a large neotropical lancehead that grows to more than 1500 mm TL. It is common in lowland and premontane moist forest up to about 1000 m elev., and is a major source of medically significant human envenomations. Available data indicate that *B. asper* feeds predominantly on rodents, but also feeds on birds, frogs, lizards, snakes (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Cornell University Press, Ithaca, New York. 870 pp.), and arthropods (Boada et al. 2005. Herpetozoa 18 [1/2]:77–79).

Here we report for the first time fish as prey for *B. asper*, and two additional findings we recovered from stomachs of specimens from Venezuela. An adult male *B. asper* (SVL = 1180 mm; MIZA 505) collected on 21 August 2006 near Estación Ecológica Guáquira, 10 km ESE of San Felipe, Estado Yaracuy, Venezuela (10.2975°N, 68.6554°W, 100 m elev.) contained an eel (*Synbranchus marmoratus*). Martins et al. (2002. *In* Schuett et. al. [eds.], Biology of the Vipers, pp. 307–328. Eagle Mountain Publishing, Eagle Mountain, Utah) examined stomach contents from 1055 specimens representing 22 species of *Bothrops* and did not record a single case of fish as prey.

MN examined the stomachs of two adult *B. asper* in the museum at the Biological Station Rancho Grande. An adult male collected at the Estación de Fauna de El Limón on 8 November 1999 (EBRG 3716) had eaten a small wren (*Troglodytes* sp.). An adult female *B. asper* (EBRG 3215) collected on 25 October 1995 at the same locality contained an amphisbaenian (*Amphisbaena alba*).

We are grateful to Carlos Rivero-Blanco, Róbert Sóliz, and Orlando Escalante for making our stay at the Estación Ecológica la Guáquira possible. SL received financial support by the German Academic Exchange Service (DAAD). Collecting permission (N 01-02-03) for La Guáquira was issued to Douglas Mora by Marcos Luis Cardozo Uzcategui, general director of the administrative bureau for permissions in the Ministerio del Ambiente y los Recursos Naturales Renovables.

IMANTODES CENCHOA (Blunt-headed Tree Snake). ***IMANTODES GEMMISTRATUS*** (Central American Tree Snake), ***IMANTODES INORNATUS*** (Western Tree Snake). **ENDOPARASITES.** Species of *Imantodes* occur in lowlands and premontane slopes from Sonora and southern Tamaulipas, Mexico south to northwestern Ecuador, Bolivia, Paraguay, and northeastern Argentina (Savage 2002. The Amphibians and Reptiles of Costa Rica. A Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago, Illinois. 934 pp.). To our knowledge there are no reports of endoparasites from any species of *Imantodes*. The purpose of this note is to establish the initial helminth lists for *Imantodes cenchoa*, *I. gemmistratus*, and *I. inornatus* from Costa Rica.

Nineteen *I. cenchoa* (SVL = 725.2 mm ± 98.2 *SD*, range = 503–843 mm); 12 *I. gemmistratus* (SVL = 597.3 mm ± 89.7 *SD*, range = 447–805 mm); 10 *I. inornatus* (SVL = 586 mm ± 47.4 *SD*, range = 502–657 mm) were borrowed from the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California and examined for helminths. The posterior third of the body cavity was opened by a longitudinal incision and organ surfaces and mesenteries were visually examined for parasites. Nematodes were identified after clearing in glycerol. Cestodes and acanthocephalans were stained in hematoxylin, mounted in Canada balsam and studied as whole-mounts. Found were: *I. cenchoa*, 5 oligacanthorhynchid cystacanths in (LACM 150789, 150791, 151332, 151339), prevalence = 21% (number infected/number examined × 100), mean intensity = 1.3 ± 0.50 SD (mean number infected individuals), range = 1–2, and 1 *Mesocestoides* sp. tetrathyridium in (LACM 151377) (prevalence = 5%); *I. gemmistratus*, 1 oligacanthorhynchid cystacanth in (LACM 150773) (prevalence = 8%); *I. inornatus*, 4 *Porrocaecum* sp. (larva in cysts) in LACM 114141, 150578 (prevalence = 20%, mean intensity = 2.0 ± 1.4 *SD*, range = 1–3) and 4 oligacanthorhynchid cystacanths in (LACM 114143, 150754) (prevalence = 20%, mean intensity = 2.0 ± 1.4 *SD*, range = 1–3). Voucher endoparasites were deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland: *I. cenchoa*, *Mesocestoides* sp. (USNPC 101518), cystacanth (USNPC 101519); *I. gemmistratus*, cystacanth (USNPC 101520); *I. inornatus*, *Porrocaecum* sp. (USNPC 101520), cystacanth (USNPC 101521). All of the above helminths have been previously found in other colubrid snakes from Costa Rica (Goldberg and Bursey 2004. Carib. J. Sci. 40:62–69).

The genus *Mesocestoides* contains cestodes in which a larval form (tetrathyridium) is infective to a predatory definitive host (Roberts and Janovy 2005. Gerald D. Schmidt & Larry S. Roberts' Foundations of Parasitology, McGraw-Hill, New York. 702 pp.). Adults of *Porrocaecum* occur in the intestines of birds; eggs are ingested by earthworms to commence development (Anderson 2000. Nematode Parasites of Vertebrates. Their Development and Transmission. CABI Publishing, Oxfordshire, UK. 650 pp.). Acanthocephalans have larvae (cystacanths) which occur in arthropod intermediate hosts (Kennedy 2006. Ecology of the Acanthocephala. Cambridge University Press, Cambridge, UK. 249 pp). The helminths found in this study do not develop beyond the larval stage in reptiles. Species of *Imantodes* presumably acquire these helminths by ingesting infected frogs (Savage 2002, *op. cit.*). *Imantodes cenchoa* represents a new host record for cystacanths and *Mesocestoides* sp.; *I. gemmistratus* a new host record for cystacanths; and *I. inornatus* a new host record for larvae of *Porrocaecum* sp. and cystacanths.

We thank C. Thacker (LACM) for permission to examine *Imantodes* sp. which are part of the CRE (= Costa Rica Expeditions) collection donated to LACM by J. M. Savage in 1998.

Submitted by **STEPHEN R. GOLDBERG**, Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); and **CHARLES R. BURSEY**, Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb@psu.edu).

LAMPROPELTIS GETULA NIGRA (Black Kingsnake). **OPHIOPHAGY**. Ophiophagy has been commonly documented for many kingsnake (*Lampropeltis*) species. For example, Black Kingsnakes have been documented to prey mainly on species of *Nerodia* and *Regina*, but also *Agkistrodon contortrix* (Copperhead) (Tilley and Huheey 2001, Reptiles and Amphibians of the Smokies, 2nd edition. Great Smoky Mountains Natural History Association, Gatlinburg Tennessee, 143 pp.).

Recently, we observed the predation of an *A. contortrix* by a *L. g. nigra* during an ongoing radiotelemetry study of Copperhead habitat use at the Bankhead National Forest, Alabama, USA. On 23 July 2006, we captured a large male Copperhead (snout–vent length 755 mm; total length 858 mm; mass 326 g) in a drift-fence trapping array located in a recently thinned pine-hardwood forest stand. We surgically implanted the snake with a transmitter (Model SI-2, 9 g, Holohil Systems Ltd., Carp Ontario) following procedures described in Reinert and Cundall (1982. Copeia. 1982:702–705). The snake was released after 48 h and relocated every three days for a total of 11 unique locations. The last visual location was on 4 September 2006 in a large stream management zone next to the thinned forest stand. For two weeks following the 4 September 2006 location, the snake was located three separate occasions; twice inside a large rockpile and once underground at the edge of a wildlife management plot. On 21 September 2006, the snake was tracked inside the base of a newly downed *Quercus alba* (White Oak) (diameter at breast height 18 cm; length 690 cm; distance from ground 25 cm), ca. 500 m from the 4 September 2006 location. The radio signal remained in the downed tree for two weeks, during which we were unable to visually confirm its status. On 5 October 2006, we detected the radio signal in the adjacent stream management zone. When approached, we found a large male Black Kingsnake (SVL 1230 mm; total length 1370 mm; mass 699 g) basking under herbaceous cover and *Fagus grandifolia* (American Beech) saplings. Radio signals emanated from the kingsnake indicating that it had consumed the Copperhead. We captured the kingsnake and brought it back to the laboratory for further observations and to retrieve the transmitter. The transmitter was palpated to the mouth and then slowly removed using tweezers. The kingsnake was returned to the point of capture after three days in captivity and behaved normally upon release.

We believe that the kingsnake predated the Copperhead prior to 21 September 2006, and sought shelter in the downed White Oak to digest the large prey. This idea is supported because the only remains of the Copperhead were a small section of ribs stuck to the transmitter surface, indicating that digestion occurred for a considerable amount of time. Our observation of snake predation not only confirms the proclivity of Black Kingsnakes for Copperheads, but also illustrates the potentials of using radiotelemetry to identify predation rates of focal species during traditional radiotelemetry studies.

Submitted by **WILLIAM B. SUTTON** (e-mail: william.sutton@mailserver.aamu.edu), **MATTHEW G. BOLUS**, and **YONG WANG**, Alabama A&M University, Department of Natural Resources and Environmental Sciences, Normal, Alabama 35762, USA.

LEIOPYTHON ALBERTISII (Northern White-Lipped Python). **BEHAVIOR**. Little is known about the diet and behavior of this species in the wild, and it has received little attention by scientists. One record on the diet of this species in the wild suggests that it primarily preys on rats (Slip and Shine 1990. Herpetologica 46:283–290), but it is assumed that juvenile pythons also prey on skinks (O'Shea 1996. A Guide to the Snakes of Papua New Guinea. Independent Publishing, Papua New Guinea. p. 80). *Leiopython albertsii* exhibits some interesting behaviors in captivity: it regularly regurgitates fur balls (Froesch 1966. DATZ 19:255); juveniles and sub-adults build persistent tunnel systems in the substrate (D. G. Barker, pers. comm.; pers. obs.) through which they move; and individuals undergo a dramatic physiological color change (pers. obs., see http://leiopython.de for details and photographs). Additionally, individuals often sleep with the head resting laterally on the body coils (pers. obs., see http://leiopython.de for details).

Here I report an unusual and interesting behavior repeatedly shown by two of my long-term captive female *L. albertisii* (12 and 15 years old), caught in the vicinity of Sorong, West Papua. Approximately three weeks after feeding an adult rat each and one week after defecating and regurgitating fur balls, the snakes were observed raising their head and neck (about ¼ of the body) as well as their tail (including the cloacae). The mouth was opened wide and the glottis was shut. Within seconds, the snake's mid-body inflated, and then deflated again accompanied by flatulence-like noise and minimum cloacal outcast of a mucilaginous substance. This was repeated four and five times, respectively. It looked as though the snakes were pumping air into their stomach, and then almost immediately releasing it through the cloaca.

To my knowledge, nothing has been reported on the digestive behavior of this species. Taking into consideration that ambush predators such as large pythons, which feed infrequently, are able to down-regulate their gastrointestinal tract after finishing digestion (Ott and Secor 2007. J. Exp. Biol. 210:340–356), this action might be a means of clearing the gastrointestinal tract prior to down-regulation. However, feces were found in other snake species in which the gastrointestinal tract already downregulated (S. Secor, pers. comm.). To the best of my knowledge, this is the first report of gastrointestinal ventilation behavior in snakes.

I thank David G. Barker and Stephen M. Secor for discussion and sharing unpublished observations.

GEOGRAPHIC DISTRIBUTION

Instructions for contributors to Geographic Distribution appear in Volume 40, Number 1 (March 2009, p. 106). Please note that the responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extension reports unless a thorough literature review has been completed.

CAUDATA — SALAMANDERS

AMBYSTOMA LATERALE (Blue-spotted Salamander). CANADA: ONTARIO: Kenora District: Wunnummin Lake (52.9335 °N, 89.2976 °W; WGS84). 17 May 2006. Ralph Winter. Verified by Robert W. Murphy (Royal Ontario Museum) and James P. Bogart (University of Guelph). Royal Ontario Museum (ROM 45416). One adult male (10.3 cm total length, 5.6 cm SVL) found dead adjacent to a pond in the Wunnumin Lake First Nation community just after spring thaw. The range of members of the Jefferson's Salamander complex in northern Ontario is poorly documented, and not well understood (Oldham and Weller 2000. Ontario Herpetofaunal Atlas. Natural Heritage Information Centre, Ontario Ministry of Natural Resources, Peterborough, Ontario, Canada. < http://www.mnr.gov.on.ca/MNR/nhic/herps/ohs.html > (updated 15 January 2001). This record extends the documented range limit for this complex at this longitude in Ontario northward by 327 km from Burnt Island (ROM 11981) in Lake Nipigon (50.0419°N, 88.4367°W). The nearest adjacent documented records for specimens of this complex are 151 km to the west at Highway 808/McCauley River Road, Kenora District (52.4515 °N, 91.3985°W; Canadian Museum of Nature, CMNAR 24489 [formerly National Museum of Canada, NMC 24489]), and 618 km to the east at Moosonee, Cochrane District (51.2833 °N, 80.6500 °W; J.P. Bogart, JPB 19712). This record suggests that the southward dip in the range in northern Ontario depicted in published maps (Conant and Collins 1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America. 3rd ed., expanded. Houghton Mifflin Co., Boston, Massachusetts. 616 pp.; Petranka 1998. Salamanders of the United States and Canada, Smithsonian Press, Washington. 587 pp.; MacCulloch 2002. The ROM Field Guide to Amphibians and Reptiles of Ontario. Royal Ontario Museum, and McClelland & Stewart, Toronto, Ontario. 168 pp.) might be an artifact of insufficient sampling in northern Ontario. In addition, ROM 45416 represents the most northern locality of Jefferson's Salamander complex salamanders identified as LL (Lowcock et al. 1987. Syst. Zool. 36:328–336) using isozyme electrophoresis (Bogart and Klemens 2008. Am. Mus. Novitates No. 3627:1–58), and is one of only five other localities for electrophoretically-determined LL in Ontario north of 48°N latitude (southwest of Thunder Bay, Thunder Bay District [JPB 23715–25, 23934, 24384–85]; Moosonee, Cochrane District [JPB 19712]; north of Harmon Generating Station, Mattagami River, Cochrane District [JPB 39596–97]; north of Kapuskasing, Mattagami River, Cochrane District [JPB 39598]; and, near New Liskeard, Timiskaming District [JPB 24172, 24175]).

AMBYSTOMA MACULATUM (Spotted Salamander). USA: ILLINOIS: Gallatin Co.: Shawnee National Forest, vernal pond ca. 1 km from Pounds Hollow Rd. on York Lane Rd. (38.603889°N, 88.262778°W; NAD 83). 08 March 2008. Cy L. Mott. SIUC H-8762. Hamilton Co.: Hamilton County State Fish and Wildlife Area, vernal pond ca. 500 m S of the Dolan Lake spillway parking lot (38.051389°N, 88.402222°W; NAD 83). 08 March 2008. Cy L. Mott. Egg mass. SIUC H-8763. Saline Co.: Saline County State Fish and Wildlife Area, forested pond ca. 100 m E of Glen Jones Road (37.691944°N, 88.378611°W; NAD 83). 08 March 2008. Cy L. Mott. Egg mass. SIUC H-8764. All specimens verified by Ronald A. Brandon. All specimens represent new county records (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, Champaign, Illinois. xii + 282 pp.). This research was funded by a grant from the Chicago Herpetological Society.

Submitted by **CY L. MOTT**, Cooperative Wildlife Research Laboratory, Department of Zoology, Southern Illinois University, Carbondale, Illinois 62901, USA; e-mail: cm8755@siu.edu.

DESMOGNATHUS AENEUS (Seepage Salamander). USA: GEORGIA: Haralson Co.: 5.79 km E of Buchanan along State Rt. 120. 23 April 1968. G. Folkerts and R. Estridge. Verified by Craig Guyer. AUM 18833–18840. New county record. Talbot Co.: Sprewell Bluff Wildlife Management Area. Seepage on the N slope of Rockhouse Mountain near the Flint River (32.88055° N, 84.50418° W; WGS 84). 15 February 2009. S. Graham and K. Gray. Verified by John Jensen. AUM 37837. New county record. Although *D. aeneus* was mentioned to occur in Haralson County (Folkerts 2004. *In* Mirarchi et al. [eds.], Alabama Wildlife Vol. 3: Imperiled Amphibians, Reptiles, and Mammals. University of Alabama Press. 225 pp.), there were no specifics or verification provided, and the locality did not appear in a recent regional guide (Jensen et al. 2008. Amphibians and Reptiles of Georgia. University of Georgia Press, Athens, Georgia. 575 pp.). The Haralson County locality is ~ 70 km from nearest documented population to the NE (Cherokee County, Georgia), and probably contiguous with nearby Alabama populations to the west (Cleburne County).

The Talbot County locality is ~ 100 km SE of the nearest documented population in Carroll County, Georgia (Williamson and Moulis 1994. Distribution of Amphibians and Reptiles in Georgia. Savannah Sci. Mus. Spec. Publ. 3:1–172), and is potentially disjunct, unless additional localities await documentation along the Talladega Uplands/Pine Mountain Ridges in western Georgia. The Talbot County record is the first for this species from the Pine Mountain Ridges ecoregion, an area within the Piedmont physiographic province (Wharton 1978. The Natural Environments of Georgia. Georgia Department of Natural Resources Bull. 113. 227 pp.; Graham et al., *in review*). The specimen was found under leaf litter near the head of a ~ 20–30 m seepage run which flows directly into the Flint River.

This collection trip was partially supported by NIH grant #R01-A149724 to T. Unnasch under Georgia collection permit

#29-WBH-08-8.

ANAXYRUS* (*=BUFO*) *WOODHOUSII (Woodhouse's Toad). USA: TEXAS: Castro Co.: 0.4 miles N of Highway 60 on FM 1057 (34.7427778ºN, 102.513055ºW), 3936 feet elev. 06 September 2008. Collected by James R. Dixon and Bob L. Tipton in an agricultural area. Verified by Toby Hibbitts. Texas Cooperative Wildlife Collections (TCWC 93122). The large male specimen was found alive on the road at 0017 h, 59ºF, adjacent to an agricultural area, about 100 yards south of the Deaf Smith County sign. Deaf Smith Co.: 12.0 miles W of Hereford on Highway 1058W (34.825833ºN, 102.608888ºW), 3969 feet elev. 05 September 2008. Verified by Toby Hibbitts. (TCWC 93121). The small male specimen was found alive at 2117 h, 65 ºF, on the road. Both specimens represent new county records (Dixon 2000. Amphibians and Reptiles of Texas. 2nd edition. Texas A&M University Press, College Station, Texas. 421 pp.).

COLOSTETHUS CAERULEODACTYLUS. BRAZIL: AMAZONAS: Canutama Municipality (06.9468333ºS, 64.2003611ºW). 24 January 2004. A. M. Batistella, A. C. Cordeiro, and O. S. Pereira, Instituto Nacional de Pesquisas da Amazônia - INPA, Manaus, Brazil, Amphibian and Reptile Collection (INPA-H 11.451–65). Verified by A. Lima. The specimens were found in the leaf litter in forest that is periodically flooded, on the right bank of Igarapé Trufarí, a black water tributary of the Purus River. This is the third known locality for this species which is endemic to the Brazilian Amazon Basin. Extends the distribution 665 km SW of the population located ca. 40 km S Manaus, elev. 50 m, Amazonas, Brazil (03.61955ºS, 60.45511ºW), in the municipality of Castanho (Lima and Caldwell 2001. Herpetologica 57:180–189).

PSEUDACRIS CRUCIFER (Spring Peeper).USA: TENNESSEE: Benton Co.: McIllwain Road, (35.853030ºN, 88.065970ºW; WGS84). 31 March 2006, H. A. Messer and L. D. Bennie, APSU 18245. Frogs were recorded calling from a woodland area adjacent to the road. APSU 18246. Additional Benton County locations (APSU 18246, APSU 18247) were also recorded. Carroll Co.: Cutlip Road (36.031727ºN, 88.601635ºW; WGS 84). 08 March 2006, H. A. Messer and L. D. Bennie, APSU 18248. Frogs were recorded calling from flooded grassland adjacent to the road. An additional Carroll County location (APSU 18249) was also recorded. Davidson Co., Luster Road (36.335686ºN, 86.782390ºW; WGS84) 14 April 2006, H. A. Messer and L. D. Bennie, APSU 18251. An additional Davidson County location (APSU 18252) was also recorded. Decator Co.: Bath Springs, Red Walnut Road at Red Walnut Church of Christ, (35.469461ºN, 88.181546ºW; UTM 84). 11 March 2006, B. P. Butterfield, K. L. Butterfield, and J. B. Butterfield, APSU 18253. Frogs were recorded calling from flooded bottomland hardwoods near North Prong of Stewman Creek. Gibson Co.: Hwy 425, (35.936590ºN, 88.736626ºW; WGS84). 08 March 2006, H. A. Messer and L. D. Bennie, APSU 18256. Frogs were recorded calling from a drainage ditch running along a railroad track that intersects with Hwy 425. An addition Gibson County location (APSU 18257) was also recorded Haywood Co.: Hatchie National Wildlife Refuge, Hillville, (35.468613ºN; 89.143466ºW;WGS84). 15 February 2005, J. Stanley, APSU 18225. Frogs were recorded calling from edge of cornfield with rain-filled depressions adjacent to woodland habitat.Henderson Co.: Hwy 100 (35.493744ºN, 88.402690ºW;WGS84). 21 February 2005, H.A. Messer and L.D. Bennie, APSU 18260. Frogs were recorded calling from a flooded area adjacent to woodlands. Additional Henderson County locations (APSU 18261 – APSU 18263) were also recorded Hickman Co.: Nunnelly Road (35.891005ºN, 87.606087ºW;WGS84). 05 April 2006, H.A. Messer and L.D. Bennie, APSU 18264. Frogs were recorded calling from a woodland adjacent to the road. Additional Hickman County locations (APSU 18265, APSU 18266) were also recorded. Humphreys Co.: Seed Tick Road (35.838549º N, 87.800247ºW;WGS84). 12 April 2006, H.A. Messer and L.D. Bennie, APSU 18267. Frogs were recorded calling from a flooded grassy area surrounded by woodlands. An additional Humphreys County location (APSU 18268) was also recorded. Lauderdale Co.: South end of Open Lake adjacent to Hwy 19 (35.779218ºN, 89.690994ºW; WGS84). 06 March 2006, H. A. Messer and L. D. Bennie, APSU 18269. Frogs were recorded calling from woodland adjacent to Open Lake. Additional Lauderdale County locations (APSU 18270, APSU 18271 andAPSU 18272) were also recorded. Lawrence Co.: 35.419429ºN, 87.476543ºW;WGS84. 13 March 2006, H. A. Messer and L. D. Bennie, APSU 18273. Several additional Lawrence County locations (APSU 18274, APSU 18275

and APSU 18276) were also recorded. LEWIS CO.: 35.429092ºN, 87.475025ºW; WGS84. 13 March 2006, H. A. Messer and L. D. Bennie, APSU 18277. Frogs were recorded calling from a pond in field adjacent to woodland. Two additional Lewis County locations (APSU 18278, 18279) were also recorded. MADISON CO., Pinson, Ozier Road (35.496319ºN, 88.712942ºW; WGS84). 03 February 2005, H. A. Messer and L. D. Bennie, APSU 18280. Frogs were recorded calling from flooded woodland. One additional Madison County location (APSU 18281) was recorded. MAURY CO.: Leaper's Creek Road (35.6996392 ºN, 87.198301W: NAD83), 05 April 2006, H. A. Messer and L. D. Bennie, APSU 18282. Frogs were recorded calling from woodland surrounding Leaper's Creek. A second Maury County location (APSU 18283) was also recorded. MCNAIRY CO.: 35.228975ºN, 88.405480ºW; WGS84. 21 February 2005, H. A. Messer and L. D. Bennie, APSU 18284. Frogs were recorded from a farm pond. Several additional McNairy County locations (APSU 18285 –APSU 18290) were also recorded. PERRY CO.: Hwy 412 next to Coon Creek (35.620755ºN, 87.734145ºW,WGS84). 13 March 2006, H.A. Messer and L.D. Bennie, APSU 18291. One additional Perry County location (APSU 18292) was also recorded. TIPTON CO.: 35.452477ºN, 89.568174ºW;WGS84. 25 February 2005, H. A. Messer and K. A. Dassatt, APSU 18293. Frogs were recorded calling from a wetland. A second Tipton County location (APSU 18294) was also recorded. WAYNE CO.: Hwy 64, 35.288515ºN, 87.980692ºW; WGS84, 13 March 2006, H. A. Messer and L. D. Bennie, APSU 18295. Frogs were recorded calling from woodland. A second Wayne County location (APSU 18296) was also recorded.

Pseudacris crucifer has a near continuous distribution throughout much of the eastern United States and southeastern Canada (Conant and Collins 1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America. 3rd ed. Houghton Mifflin Co., Boston, Massachusetts). However, this common species has not been reported from many counties in central and west Tennessee (Butterfield et al. 2005. *In* M. Lannoo (ed.), Amphibian Declines: The Conservation Status of United States Species, pp. 472–474. University of California Press, Berkeley). The purpose of this study was to determine if the distribution map provided by Butterfield et al. (*op. cit.)* accurately reflects the distribution of *P. crucifer* in Tennessee or is the result of inadequate sampling. Sampling was conducted during the breeding seasons of 2004, 2005, and 2006. Topographic maps were used to identify likely breeding sites within each county.

All voucher specimens (audio recordings and/or photographs) are deposited in the Austin Peay State University Museum of Zoology (APSU) and were verified by A. Floyd Scott. Collections were made under the authority of TWRA permit 1494 to BPB. All records, represent new county records for *P. crucifer* in Tennessee (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee).We thank A. Floyd Scott for verifying recordings and Freed-Hardeman Research Center and Freed-Hardeman University Honors College for providing funding.

PHRYNOPS GIBBUS (Gibba Turtle). BRAZIL: AMAZONAS: Barreirinha (02.9457ºS, 57.0239ºW; WGS84). 08 May 2008. L. Schneider, C. Ferrara, R. C. Vogt, L. B. Santos-Junior. Verified by L. Bonora. Coleção de Repteis e Anfibios, Instituto Nacional de Pesquisas da Amazonia INPAH 19956. The range of this secretive species is poorly documented, known from throughout the Guianas and the Brazilian northern coastal plain as well as the Amazon drainage of Colombia, Venezuela, and Peru (Vogt 2008. Tortugas Amazónicas. Grafica Biblos, Lima, Peru 104 pp.). This is the first state record, and extends the range 740 km W from the nearest location in Breves, Para state (01.6825ºS, 50.48ºW; WGS84) based on MZUSP 2684–5 (Pritchard and Trebbau. 1984. The Turtles of Venezuela. Society for the Study of Amphibians and Reptiles, Oxford, Ohio. 403 pp.). Extends the range of this species into the central Amazon Basin in Brazil. The turtles were hand captured in 20–30 cm deep, clear water, forest pools.

Submitted by **LARISSA SCHNEIDER** (e-mail: laribio@terra.com.br), **CAMILA FERRARA**, **RICHARD C. VOGT**, **LADISLAU B. SANTOS-JUNIOR**, Instituto Nacional de Pesquisas da Amazônia (INPA), Caixa Postal 478, CEP 69011-970, Manaus, Amazonas, Brazil.

PLATEMYS PLATYCEPHALA (Twist-necked Turtle). BRAZIL: AMAZONAS: Barreirinha (02.9457ºS, 57.0239ºW; WGS84). 08 May 2008. C. Ferrara, L. Schneider, R. C. Vogt, and L. B. Santos-Junior. Verified by L. Bonora. Coleção de Repteis e Anfibios, Instituto Nacional de Pesquisas da Amazonia INPAH 19957. Turtle was in a shallow forest pool (20–30 cm deep) in the middle of the high evergreen rain forest. First record for this municipality. The closest record is in Maués, Amazonas (03.54ºS, 57.6916ºW; WGS84), based on AMNH 89782, 100 km SW from this new record (Ernst 1983. J. Herpetol. 17:345–355). This record fills in the gap between Santarem, Para, and Maués, Amazonas, adding another locality south of the Amazon River in the Central Amazon Basin.

Submitted by **CAMILA FERRARA** (e-mail: ferrara@terra.com.br), **LARISSA SCHNEIDER**, **RICHARD C. VOGT**, **LADISLAU B. SANTOS-JUNIOR**, Instituto Nacional de Pesquisas da Amazônia (INPA), Caixa Postal 478, CEP 69011-970, Manaus, Amazonas, Brazil.

RHINOCLEMMYS PUNCTULARIA (Spot-legged Turtle). AMAZONAS, Barreirinha. (02.9457ºS. 57.0239º W; WGS84). 08 May 2008. L. Schneider, C. Ferrara, R. C. Vogt, L. B. Santos-Junior. Verified by L. Bonora. Coleção de Repteis e Anfibios, Instituto Nacional de Pesquisas da Amazonia. INPAH 19958. This is the fourth record for the Amazonas state (Vogt 2008. Tartarugas da Amazônia. Grafica Biblos, Lima, Peru. 104 pp.). This new record extends the range for this species 236 km SW from the closest record in Santarém, Pará (MZUSP 39) (02.5455ºS, 54.9688ºW; WGS84) (Pritchard and Trebbau 1984. The Turtles of Venezuela. Society for the Study of Amphibians and Reptiles, Oxford, Ohio. 403 pp.). Turtle was captured in Tucumanduba village by muddling with help of a local collector, Sr. Bico.

Submitted by **LARISSA SCHNEIDER** (e-mail: laribio@terra.com.br), **CAMILA FERRARA, RICHARD C. VOGT, LADISLAU B. SANTOS-JUNIOR**, Instituto Nacional de Pesquisas da Amazônia (INPA), Caixa Postal 478, CEP 69011-970, Manaus, Amazonas, Brazil.

TRACHEMYS SCRIPTA ELEGANS (Red-eared Slider). USA: OHIO: Delaware Co.: Liberty Township: Pond at Columbus Zoo and Aquarium (40.156799°N, 83.119469°W; WGS 84). 12 March 2007. Jeffrey E. Dawson. Verified by Jeffrey G. Davis. Photo voucher in Cincinnati Museum Center, Geier Collections and Research Center (CMC HP 588). New county record (Wynn and Moody 2006. Ohio Turtle, Lizard, and Snake Atlas. Ohio Biol. Surv. Misc. Contr. No. 10, Columbus. iv + 81 pp.). *T. s. elegans* have been released into scattered localities around Ohio; the nearest previous record is ca. 60 km E in Licking County (Wynn and Moody, *op. cit.*). During the 1970s and early 1980s, *T. s. elegans* that were donated to the Columbus Zoo by visitors were released into an unenclosed pond by zoo keepers. Although this practice no longer continues, a number of individuals are still present in the pond. Hatchling *T. s. elegans* have been seen on multiple occasions in recent years, suggesting that this population is successfully reproducing, but whether any offspring survive to maturity is currently unknown. Most recently, a hatchling was found 6 May 2008 on zoo grounds near the Scioto River (less than 200 m straight-line distance from the pond). We thank Mike Brittsan, Curator of Shores at the Columbus Zoo and Aquarium, for bringing the recent hatchling to our attention.

Submitted by **JEFFREY E. DAWSON** (e-mail: jeff.dawson@columbuszoo.org) and **RONNIE E. HATCHER** (e-mail: ron.hatcher@columbuszoo.org), Reptiles/Shores Region, Columbus Zoo and Aquarium, 4850 W. Powell Road, P. O. Box 400, Powell, Ohio 43065, USA.

SQUAMATA – LIZARDS

ANOLIS CAROLINENSIS CAROLINENSIS (Northern Green Anole). USA: ARKANSAS: Johnson Co.: Clarksville, 1.6 km N Clark Rd. (34.192672°N, 94.064072°N; NAD 83). 04 November 2008. T. Kremers. Verified by S. E. Trauth. Arkansas State University Herpetological Museum (ASUMZ 31281). Specimen is an adult female, 60 mm SVL. New county record and first locality in the state north of the Arkansas River and west of the boundary separating the Interior Highlands/Gulf Coastal Plain (Trauth et al. 2004. Amphibians and Reptiles of Arkansas. Univ. Arkansas Press, Fayetteville. 421 pp.). Most importantly, we document the northernmost record for *A. c. carolinensis* in the United States west of the Mississippi River (Conant and Collins 1998. Reptiles and Amphibians of Eastern and Central North America. 3rd ed., expanded. Houghton Mifflin Co., Boston, Massachusetts. 616 pp.).

ANOTOSAURA VANZOLINIA. BRAZIL: BAHIA: Municipality of Rui Barbosa, Quixadá farm (12.2708ºS, 40.3731ºW), 550 m elev. 20 June 2003. L. E. Moisés. Museu de Zoologia da Universidade Estadual de Santa Cruz, Ilhéus, Bahia, Brazil (MZUESC 4119). Collected during daylight hours, on the ground of the estacional forest. Verified by M. Rodrigues. Previously known from northeastern Brazil in Agrestina and Serra Negra municipality, Pernambuco state (Delfin and Freire 2007. Oecol. Bras. 11[3]:365–382). First state record, extends distribution ca. 750 km S from Pernambuco state (Delfin and Freire 2007, *op. cit.*).

Submitted by **MARCO ANTÔNIO DE FREITAS,** Programa de pós-graduação em zoologia, Universidade Estadual de Santa Cruz, CEP 46.500-000 Rodovia Ilhéus/Itabuna, Ilhéus, Bahia, Brazil (e-mail: philodryas@hotmail.com); and **LUIZ EDUARDO MOISÉS,** Pituba, Salvador, Bahia, Brazil, CEP 42-700-000 (e-mail bioengen@yahoo.com.br).

ASPIDOSCELIS XANTHONOTA (Red-backed Whiptail). MÉXICO: SONORA: Caborca: Sierra La Gloria-Cerro El Alamo, (30.5055°N, 112.051°W; WGS84), 521 m elev. 27 August 2008. UAZ 57076-PSV, 57077-PSV. Sonoyta: Sierra Cubabi (31.4333°N, 112.5038°W; WGS 84), 755 m elev. 02 August 2008. UAZ 57078-PSV. Philip C. Rosen and Adrian Quijada-Mascareñas. All verified by George Bradley. New records for México and a range extension of ca. 120 km S (airline) from the closest known locality in Arizona (Brennan and Holycross 2006. A Field Guide to Amphibians and Reptiles in Arizona. Arizona Game and Fish Department, Phoenix. 150 pp.). Liner (2007. Louisiana State Univ. Occ. Pap. Mus. Nat. Sci. 80:1–60) lists *A. xanthonota* as occurring in Mexico, but museum searches and queries to curators have not revealed any previous records. The lizards were found in Arizona Upland Sonoran Desert scrub on rocky slopes, confirming a widespread occurrence in this vegetation formation (Rosen 2007. *In* R. S. Felger and B. Broyles [eds.], Dry Borders: Great Natural Reserves of the Sonoran Desert, pp. 310–337. Univ. Utah Press, Logan).

Submitted by **PHILIP C. ROSEN** and **ADRIAN QUIJADA-MASCARENAS**, School of Natural Resources, University of Arizona, 316 Biosciences East, Tucson, Arizona 85721, USA; e-mail: pcrosen@email.arizona.edu.

SQUAMATA — SNAKES

CARPHOPHIS AMOENUS (Eastern Wormsnake). USA: GEORGIA: Madison Co.: John Seginak property, off Waggoners Grove Church Rd. (34.035047°N, 83.170878°W; WGS 84). 02 April 2006. Collected during undergraduate herpetology class survey by E. Adair, P. Barnett, A. Durso, K. Holcomb, N. Hyslop, N. Loftin, A. Ruiz, and D. van Dijk. Verified by Kenneth L. Krysko. UF 154592. New county record (Jensen et al. 2008. Amphibians and Reptiles of Georgia. The University of Georgia Press. 575 pp.). An adult *C. amoenus* measuring 182 mm SVL was found inside a log adjacent to a riparian wetland. This record is ca. 18.82 km SSE of three 1953 records from Oglethorpe County, Georgia (GMNH 254).

Submitted by **ANDREW M. DURSO**, University of Georgia, Odum School of Ecology, Athens, Georgia 30602, USA (e-mail: amdurso@gmail.com); **KERRY L. HOLCOMB**, 1207 Somerton Place, Cumming, Georgia 30040, USA (e-mail: holcombkerryl@gmail.com); and **PARKER G. BARNETT**, 119 Ashley Way, Jefferson, Georgia 30549, USA (e-mail: barnettp@warnell.uga.edu).

CHIRONIUS FLAVOLINEATUS (Cipó Snake). BRAZIL: CEARÁ: Barbalha Municipality: RPPN Parque do Arajara. (7.328774ºS, 39.408052ºW; WGS84). June–July1997. D.A.N. Machado. Collection of Herpetology of Núcleo Regional de Ofiologia (NUROF) - Universidade Federal do Ceará, Fortaleza, Brazil (CHUFC 2127). Verified by F. L. Franco. First state record; extends known distribution ca. 512 km airline W of João Pessoa municipality, Paraíba (7.439143ºS, 34.913502ºW; WGS84) Paraíba (Santana et al. 2008. Biotemas 21[1]:75–84; Sousa and Nóbrega 2007. Herpetofauna Terrestre de Áreas Sobre Influência da Linha de Transmissão (LT) 230 KV PE/PB, circuito 3. Anais do VIII Congresso de Ecologia do Brasil); also is the first record from Atlantic forest relicts on highlands on the State of Ceará.

Submited by **DIVA MARIA BORGES-NOJOSA**, Universidade Federal do Ceará, NUROF-UFC, Campus do Pici, Bloco 905, 60455-760, Fortaleza, Ceará, Brazil (e-mail: dmbnojosa@yahoo.com.br); and **DANIEL CASSIANO LIMA**, Universidade Estadual do Ceará, Av Mons. COLUBER CONSTRICTOR (North American Racer). USA: ILLINOIS: Hamilton Co.: Illinois Route 142, ~3 km S of McLeansboro, DOR. (38.068056°N, 88.534167°W; NAD 83). 09 August 2008. Cy L. Mott. Verified by Ronald A. Brandon. SIUC R-3459. New county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, Champaign, Illinois. xii + 282 pp.). This research was funded by a grant from the Chicago Herpetological Society.

Submitted by **CY L. MOTT**, Cooperative Wildlife Research Laboratory, Department of Zoology, Southern Illinois University, Carbondale, Illinois 62901, USA; e-mail: cm8755@siu.edu.

COLUBER CONSTRICTOR FLAVIVENTRIS (Eastern Yellow-bellied Racer). USA: TEXAS: Van Zandt Co.: DOR 78 cm SVL snake was found at the junction of Van Zandt County Roads 2708 and 2705, 22 May 2008. R. Michael Burger. Verified by Carl J. Franklin. Color digital photo vouchers, University of Texas at Arlington - Amphibian and Reptile Diversity Research Center (UTADC 2608–2611). New county record (Dixon 2000. Amphibians and Reptiles of Texas. 2nd ed. Univ. of Texas A&M Press, viii + 421 pp.).

Submitted by **R. MICHAEL BURGER**, 510 VZCR 2721, Mabank, Texas 75147, USA; e-mail: mvburger@dctexas.net.

CROTALUS VIRIDIS (Prairie Rattlesnake). USA: TEXAS: Parmer Co.: Found on Hwy 2298 at jct with Texas 214 (34.7275ºN, 102.725277ºW), 4066 feet elev. 05 September 2008. Verified by Toby Hibbitts. Texas Cooperative Wildlife Collection-Texas A&M University (TCWC 93123). New county record. (Dixon 2000. Amphibians and Reptiles of Texas. 2nd ed. Texas A&M University Press, College Station, Texas. 421 pp.). The snake was a male (SVL 652 mm, tail 54 mm) and was found DOR at 2202 h, 63ºF.

Submitted by **BOB L. TIPTON** (e-mail: btipton39@comcast.net) and **JAMES R. DIXON** (e-mail: jrdixon5@verizon.net), Texas Cooperative Wildlife Collections, Department of Wildlife and Fisheries Sciences, Texas A&M University, 2258 Tamu, College Station, Texas 77843-2258, USA.

DIADOPHIS PUNCTATUS (Ring-necked Snake). USA: ILLINOIS: Gallatin Co.: Shawnee National Forest, ca. 1 km from Pounds Hollow Rd. on York Lane Rd. (37.603889°N, 88.262778°W; NAD 83). 07 June 2008. Cy L. Mott. Verified by Ronald A. Brandon. SIUC R-3460. New county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, Champaign, Illinois. xii + 282 pp.). This research was funded by a grant from the Chicago Herpetological Society.

Submitted by **CY L. MOTT**, Cooperative Wildlife Research Laboratory, Department of Zoology, Southern Illinois University, Carbondale, Illinois 62901, USA; e-mail: cm8755@siu.edu.

EUNECTES MURINUS (Anaconda). BRAZIL: CEARÁ: Aquiraz Municipality: Tupuiu Mangroove. (03.52806°S 38.234661°W; WGS84). 22 October 2008. S. V. Mendonça. Collection of Herpetology of Núcleo Regional de Ofiologia (NUROF) - Universidade Federal do Ceará, Fortaleza, Brazil (CHUFC 3054). Verified by D. M. Borges-Nojosa. First state record; extends known distribution ca. 490 km airline E of previously known range within Maranhão (02.390187°S, 43.524319°W; WGS84), and 680 km airline northwest from Paraíba (07.136732ºS, 34.860413ºW; WGS84). This species was previously known from Amazon Forest, Atlantic Forest, Pantanal and coastal areas of much of northern South America (Cunha and Nascimento 1978. Publicações Avulsas do Museu Paraense Emílio Goeldi 31:1-218; Henderson et al. 1995. Herpetological Natural History 3:15-27; Marques et al. 2005. Serpentes do Pantanal. Holos, Ribeirão Preto. 184 pp.). The specimen was found on *gamboa* area of mangrove environment, inter dunes. Another individual was photographed on 14 May 2007 by S.V. Mendonça in this same locality. The name *sucurijuba* is used by the local peoples living in the coastal areas of Ceará with descriptive references clearly related to the *Eunectes murinus*, where some people have skins of this species hanging in their homes.

Submitted by **SANJAY VEIGA MENDONÇA** (e-mail: sanjaydomato@hotmail.com), **HUGO FERNANDES-FERREIRA** (e-mail: hugofernandesbio@gmail.com), and **RONO LIMA CRUZ** (e-mail: ronolc@gmail.com), Universidade Federal do Ceará, NUROF-UFC, Campus do Pici, Bloco 905, 60455-760, Fortaleza, Ceará, Brazil.

LEPTOTYPHLOPS BORAPELIOTES (NCN). BRAZIL: CEARÁ: Aratuba (04.411111ºS, 39.039722ºW; WGS84). 30 August 2007. S. Veiga. Instituto Butantan, São Paulo, Brazil (IBSP 76987). Verified by F. Franco. First state record, extends distribution ca. 390 km NW from of the nearest locality, Junco do Seridó in Paraíba (Vanzolini 1996. Pap. Avul. Zool. 39[15]:281–291).

Submitted by **IGOR JOVENTINO ROBERTO**, Aquasis –Associação de Pesquisa e Preservação de Ecosssistemas, Praia de Iparana s/n (Sesc Iparana), 61627-010, Caucaia, Ceará, Brazil (e-mail: igorjoventino@yahoo.com.br.); and **SANJAY VEIGA**, Sítio Vashana, Aratuba, Ceará, Brazil.

LEPTOTYPHLOPS BRASILIENSIS (Blind Snake). BRAZIL: CEARÁ: Crato Municipality: Floresta Nacional do Araripe. (7.394083°S, 39.499883°W; WGS84). 15 April 1998. D. M. Borges-Nojosa, C. A. Oliveira and A. P. B. Maia. Collection of Herpetology of Núcleo Regional de Ofiologia (NUROF) - Universidade Federal do Ceará, Fortaleza, Brazil (CHUFC 3122, adult, 146 mm SVL, 12.75 mm TL, 194 dorsals, and 18 subcaudals). Verified by F. L. Franco and U. Caramaschi. *L. brasiliensis* is considered rare, and only four previous records are known. First state record, extends the distributional range ca. 798 km NE of Barreiras-BA (12.148250°S, 44.993660°W; WGS 84) (Rodrigues and Puorto 1994. J. Herpetol. 28: 393–394). The specimen was found at Chapada do Araripe in an area of transition between habitats of Cerrado and Caatinga in a phytofisionomy designated as Carrasco.

Submitted by **DIVA MARIA BORGES-NOJOSA** (e-mail: dmbnojosa@yahoo.com.br), **CACIANA DE ALENCAR OLIVEIRA** and **ANA PATRÍCIA BEZERRA MAIA,** Universidade Federal do Ceará, NUROF-UFC, Campus do Pici, Bloco 905, 60455-760, Fortaleza, Ceará, Brazil.

NERODIA RHOMBIFER (Diamondback Watersnake). USA: TEXAS: Garza Co.: 6.84 air km S, 5.59 air km E of jct US 84 and US 380 (33.104950°N, 101.264250°W; WGS 84). 09 August 2008. Michael L. Treglia and Oswaldo Ramirez. Verified by Toby J. Hibbits. Texas Cooperative Wildlife Collection, TCWC 93119. New county record (Dixon 2000. Amphibians and Reptiles of Texas, 2nd ed. Texas A&M University Press, College Station, Texas. 421 pp.). Voucher specimen found dead at south edge of a pond, coiled against a log. Six live individuals were also observed.

Submitted by **MICHAEL L. TREGLIA** (e-mail:mlt35@tamu.edu) and **OSWALDO RAMIREZ**, Department of Wildlife and Fisheries Sciences, 2258 TAMU, Texas A&M University, College Station, Texas 77843-2258, USA.

NERODIA SIPEDON (Northern Watersnake). USA: MINNESOTA: Olmsted Co.: North Branch Root River, upstream from County Road 116 crossing (91.44.0789909°N, 91.6828156°W; NAD 83). 27 July 2006. Philip Cochran, Bridget Emmett, Amanda Frost, and Stephen Schmitt. James Ford Bell Museum (JFBM R15179). Verified by Kenneth H. Kozak. One of two individuals observed. Not documented in this county since prior to 1960 (Oldfield and Moriarty 1994. Amphibians & Reptiles Native to Minnesota. University of Minnesota Press, Minneapolis, Minnesota. 237 pp.); the specimen listed for this county by Gibbons and Dorcas (2004. North American Watersnakes: A Natural History. University of Oklahoma Press, Norman, Oklahoma. 438 pp.) was collected in 1938, also from the North Branch Root River (Benjamin Lowe, James Ford Bell Museum, pers. comm.).

Fieldwork during July and August 2004 yielded new distributional records in Quebec and Labrador at the northern range limits of two amphibians. These findings represent new county records in remote regions of Northeastern Canada, where herpetofaunal distributions are poorly documented (Bider and Matte 1996; Maunder 1983, 1997; Petranka 1998). The new localities are from rivers and streams that cross under roads, with deciduous trees and shrubs along the banks and surrounding forest consisting primarily of Black Spruce (*Picea mariana*). Amphibians were found along the margins of these waterways or on the seepage slopes just above them.

Northern Two-lined Salamanders, *Eurycea bislineata*, were located underneath various sized cover objects, including rocks and logs, and were captured by hand. In Labrador, several individuals of *E. bislineata* were commonly found under the same cover object. In one instance, 12 mature salamanders were found under a single rock measuring 40 × 30 × 30 cm. These new records of *E. bislineata* help to clarify the northern extent of its range and bridge together known populations in Labrador and Quebec. Previously, known populations were separated by upwards of 300 km (Cook and Preston 1979; Maunder 1983, 1997). The new records indicate that the distribution of *E. bislineata* is continuous from Quebec through to Labrador and along the 53°N parallel.

A gap in the distribution of *E. bislineata* still appears to exist, however, in an area extending from 16 km E of Labrador City to 29 km E of Churchill Falls. Intensive sampling in this area did not uncover any salamanders. In this area, Black Spruce dominates the forests nearly exclusively, and peat bogs cover much of the landscape. East of Churchill Falls, however, there is a dramatic change in landscape as deciduous trees often outnumber Black Spruce, the ground is noticeably rockier and there is greater elevational variation.

In northwestern Quebec, a population of *E. bislineata* was also found along Highway 113 in Jamésie Territory. This new locality is ca. 110 km SW of the nearest known population in Chibougamau and falls well within the large distribution gap noted by Bider and Matte (1996).

During this work, a single American Toad, *Anaxyrus americanus,* was found near the edge of a rocky river in Labrador, ca. 75 km from the closest previously recorded population of this species. This record is significant as the site occurs in the middle of an apparent distribution gap on the map presented by Maunder (1997). The finding connects two otherwise disjunct pockets of

populations on either side of Labrador and might indicate that *A. americanus* is present across the region.

All field collections were made by T. M. Markle and sanctioned by permits from the Province of Quebec and the Province of Newfoundland and Labrador. Collections were documented with voucher specimens. The toad was further documented with a photograph. All voucher specimens are deposited in McGill University's Redpath Museum (RM), Montreal, Quebec, Canada. Voucher identifications were verified by Shavonne Meyer. Common nomenclature follows that of Crother et al. (2008) in accordance with Frost et al. (2006).

Caudata — Salamanders

Eurycea bislineata (Northern Two-lined Salamander). CANADA: QUEBEC: Caniapiscau Regional County Municipality (RCM): 64 km S of Labrador City (80 km S of nearest recorded population in Labrador), Hwy 389 (52.669358°N, 67.40975°W). 11 July 2004. T. Markle. RM 4904. Caniapiscau RCM: 86 km S of Labrador City, Hwy 389 (52.49675°N, 67.43175°W). 11 July 2004. T. Markle. RM 4905. Caniapiscau RCM: 172 km S of Labrador City, Hwy 389 (52.059778°N, 68.64325°W). 11 July 2004. T. Markle. RM 4906, 4907. Manicouagan RCM: 337 km S of Labrador City, Hwy 389 just N of Manic 5 (50.890722°N, 68.64325°W). 11 July 2004. T. Markle. RM 4897 (larvae). Manicouagan RCM: Hwy 389, river between two lakes, ca. 100 km N of Baie-Comeau, (49.852692°N, 68.746472°W). 06 July 2004. T. Markle. RM 4896. Manicouagan RCM: Hwy 138, small stream between two lakes flowing under hwy, ca. 7 km E of turnoff to Godbout, (49.390972°N, 67.600556°W). 04 July 2004. T. Markle. RM 4893. Sept-Rivières RCM: Reserve Faunique de Port-Cartier-Sept-Iles, 7 km inside entrance to reserve, off of Hwy 138 by Port-Cartier, (50.093806°N, 67.037278°W). 05 July 2004. T. Markle. RM 4894 & 4895. Jamésie Territory: Hwy 113, small stream 7 km S of Waswanipi (49.640056°N, 76.004889°W). 29 August 2004. T. Markle. RM 6004.

Eurycea bislineata (Northern Two-lined Salamander). CANADA: NEWFOUNDLAND AND LABRADOR: Central Labrador: 29 km west of HVGB town limits (60 km from nearest known population), Hwy 500, "Lower Brooke" (53.268528°N, 60.894222°W). 10 July 2004. T. Markle. RM 4928. Central Labrador: 195 km W of HVGB (40 km from nearest known population), Hwy 500, "East Wilson River" (53.309333°N, 62.919528°W). 10 July 2004. T. Markle. RM 4930.

Anura — Frogs

Anaxyrus americanus (American Toad). CANADA: NEWFOUNDLAND and LABRADOR: Central Labrador: 195 km W of Happy Valley Goose Bay, Hwy 500, "East Wilson River" (53.309333°N, 62.919528°W). 10 July 2004. T. Markle. RM 4980 (photographic voucher).

Acknowledgments.—We thank Erin King for field assistance and John Maunder for advice. All work with animals conformed to McGill University Animal Use Protocol No. 8569 issued to DMG. This work was supported by a Discovery Grant to DMG from NSERC Canada.

The geographic distribution of amphibian and reptile species in Illinois has been well documented by Smith (1961), Phillips et al. (1999), and by numerous notes and articles published in *Herpetological Review*. However, southeastern Illinois has received less attention by herpetologists than other parts of the state. A lack of large universities, natural history museums, and the area's rural nature are all likely factors that have affected herpetological collecting in this region. Two natural divisions encompass southeastern Illinois, the Southern Till Plain Natural Division and the Wabash Border Natural Division. The Southern Till Plain Natural Division is divided into two sections. Originally mostly prairie, the Effingham Plain Section is a flat plain drained by the Embarras, Kaskaskia and Little Wabash rivers; uplands of this section are characterized by Post Oak (*Quercus stellata*) flatwoods (Schwegman et al. 1973) and upland oak–hickory

forests. The Mount Vernon Hill Country Section has rolling, hilly topography and historically was covered with upland forest (Schwegman et al. 1973). The Wabash Border Division includes the bottomlands of the Wabash River and its major tributaries and the loess-covered uplands bordering the Wabash River (Schwegman et al. 1973). The Wabash Border Division is divided into three sections; two of these sections are pertinent to the present article. The Bottomlands Section encompasses the bottomland forests, sloughs, marshes, and oxbow lakes in the floodplains of the Wabash River, the Ohio River, and their major tributaries (Schwegman et al 1973). The Southern Uplands Section of the Wabash Border Division contains the dry-mesic and mesic upland forests on the deep loess bluffs along the Wabash River (Schwegman et al. 1973).

Herein, we report amphibian and reptile records from the counties of Clay, Crawford, Hamilton, Jasper, Lawrence, Marion, and Wayne in southeastern Illinois. All specimens are new county records unless otherwise indicated (e.g., photographic voucher updated with voucher specimen) and all specimens are deposited in the Illinois Natural History Survey (INHS) Amphibian and Reptile collection. County records were determined by consulting Phillips et al. (1999), checking databases located at the Illinois Natural History Survey, and checking issues of *Herpetological Review* (March 1998–June 2008). All georeferenced localities are based on NAD83 datum. Identifications were confirmed by C. A. Phillips. Scientific and standard English names follow Crother et al. (2008).

Caudata – Salalmanders

Ambystoma maculatum (Spotted Salamander). Hamilton Co.: Hamilton County Conservation Area (38.065°N, 88.3918°W). 27 March 2008. T. L. Esker. INHS 20860. An adult collected in shallow pond. A second Hamilton County specimen (INHS 20862) was also collected. Wayne Co.: Sam Dale Lake Conservation Area (38.5432°N, 88.5928°W). 20 March 2007. T. L. Esker. INHS 20493–20494. Two males collected in a woodland pond. Two additional adults (INHS 20508–20509) were collected at a second Wayne County location.

Ambystoma opacum (Marbled Salamander). Crawford Co.: SW of Hardinville, forest E of Big Creek, N of the Embarras River, and W of Co. Rd. 400E (38.8963°N, 87.8726°W). 03 October 2006. J. E. Petzing and T. L. Esker. INHS 20144. Adult male under log in floodplain forest; Hamilton Co.: Hamilton County Conservation Area (38.0606°N, 88.3921°W). 30 March 2005. T. L. Esker. INHS 19811. Young of the year collected from a vernal pond. Mott (2008) recently reported *A. opacum* from Hamilton County. We report this specimen as an addition to Mott's county record; our collection date precedes Mott's county record by nearly three years. Lawrence Co.: NW of Russellville (38.8340°N, 87.5535°W). 14 October 2005. T. L. Esker, J. E. Petzing, and B. R. Edgin. INHS 19665. Adult male collected under log in dry, forested wetland basin.

Ambystoma texanum (Small-mouthed Salamander). Hamilton Co.: Ten Mile Creek State Fish and Wildlife Area (38.0687°N, 88.6198°W). 20 April 2005. T. L. Esker. INHS 19810. Larva collected from vernal pond in upland oak-hickory forest, raised through metamorphosis. Wayne Co.: ca. 2.35 km NW of Golden Gate, IL Rt. 15 bridge at the Little Wabash River (38.3724°N, 88.2305°W). 20 March 2007. T. L. Esker. Two adults. INHS 20560 –20561.

Ambystoma tigrinum (Tiger Salamander).Wayne Co.: Sam Dale Lake Conservation Area (38.5365°N, 88.5787°W). 2006. T.L. Esker. Larva collected from shallow pond and reared through metamorphosis. INHS 20810.

Plethodon glutinosus (Northern Slimy Salamander). Clay Co.: Martin T. Snyder Memorial Nature Preserve (38.6375°N, 88.5278°W). 31 March 2006. T. L. Esker. INHS 19948–19949. Two individuals collected in upland oak-hickory forest.

Anura — Frogs

Anaxyrus (=*Bufo*) *fowleri* (Fowler's Toad). Lawrence Co.: Robeson Hills Nature Preserve (38.7093°N, 87.5348°W). 15 August 2006. T. L. Esker and T. Buhnerkempe. INHS 20239. Individual collected in wet/mesic beech-maple forest.

Pseudacris crucifer (Spring Peeper). Hamilton Co.: Ten Mile Creek State Fish andWildlife Area (38.0680°N, 88.6176°W). 10 July 2006. J. E. Petzing, T. L. Esker, and T. Buhnerkempe. INHS 20856. Adult collected in forest.

Rana clamitans (Green Frog). Lawrence Co.: NW of Russellville (38.8335°N, 87.5544°W). 14 October 2005. B. R. Edgin, J. E. Petzing, and T. L. Esker. INHS 19666. Juvenile (possible young of the year) collected under log in dry, forested wetland basin.

Testudines — Turtles

Chelydra serpentina (Snapping Turtle). Crawford Co.: SW of Hardinville, NNE of confluence Big Creek and the Embarras River (38.9012°N, 87.8708°W). 12 June 2006. T. L. Esker. INHS 20201. Individual collected in floodplain forest with bottomland sloughs.

Trachemys scripta (Pond Slider). Jasper Co.: Sam Parr State Park (39.0309°N, 88.1164°W). 15 August 2006. T. L. Esker and T. Buhnerkempe. INHS 20659. Male collected in upper cove of Sam Parr Lake. This specimen upgrades the photographic record reported in Petzing et al. (2000); Lawrence Co.: Red Hills State Park (38.7288°N, 87.8378°W). 16 August 2006. T. L. Esker and T. Buhnerkempe. INHS 20150. Immature male collected in man-made lake.

Sternotherus odoratus (Eastern Musk Turtle). Clay Co.: 22.5 km E of Salem, Greendale Reservoir (= Greendale Lake). 11 June 1971. G. McNaughton. INHS 9846. Adult female found on shore. The locality information for this specimen was entered in the hard copy catalog as "near Iuka" in Marion County. McNaughton's field notes were found on file at the Illinois Natural History Survey with the Greendale Reservoir information. Greendale Lake is just east of the Marion County line in neighboring Clay County; Hamilton Co.: Hamilton County Conservation Area. Female collected in spillway pool of L. P. Dolan Lake/Lick Creek (38.0563°N, 88.4042°W). 10 July 2006. J. E. Petzing, T. Buhnerkempe, and T.L. Esker. INHS 20116. Jasper Co.: Sam Parr State Park (39.0113°N, 88.1195°W). 16 August 2006. T. L. Esker and T. Buhnerkempe. INHS 20151. Male collected in creek below dam. This specimen upgrades the photographic record reported by Olson (1999); Marion Co.: Stephen A. Forbes State Park (38.7093°N, 88.7458°W). 11 March 2006. T. L. Esker. INHS 19968. Hatchling collected from man-made pond on Illinois Natural History Survey Fish Research Laboratory.

Squamata — Lizards

Plestiodon (=*Eumeces*) *fasciatus* (Common Five-lined Skink). Crawford Co.: SW of Hardinville, forest E of Big Creek, N of the Embarras River, and W of County Rd. 400E (38.8957°N, 87.8723°W). 16 June 2006. T. Buhnerkempe. INHS 20041. Subadult/young adult collected in floodplain forest.

Plestiodon (=*Eumeces*) *laticeps* (Broad-headed Skink). Hamilton Co.: E of Dahlgren, Karcher's Post OakWoods Nature Preserve (38.2072°N, 88.6176°W). 10 July 2006. T. Buhnerkempe, J. E. Petzing, and T. L. Esker. INHS 20086. Adult collected on downed tree.

Squamata — Snakes

Heterodon platirhinos (Eastern Hog-nosed Snake). Marion Co.: Stephen A. Forbes State Park (38.7358°N, 88.7738°W). 07 May 2005. T. L. Esker. INHS 19586. DOR adult; head and neck vouchered.

Storeria occipitomaculata (Red-bellied Snake). Crawford Co.: Crawford County Conservation Area (39.0987°N, 87.6983°W). 4 April 2006. T. L. Esker. INHS 19954. Juvenile collected in upland mesic oak forest.

Thamnophis sauritus (Eastern Ribbonsnake). Crawford Co.: NE of Green Brier and W of Big Creek on County Rd. 450N (38.9162°N, 87.8884°W). 03 October 2006. T. L. Esker and J. E. Petzing. INHS 20143. DOR adult male. Wayne Co.: ca. 6.75 km NE of Mount Erie (38.5476°N, 88.1640°W). 23 April 2007. T. L. Esker. INHS 20532. Adult collected in floodplain forest.

Acknowledgments.—We thank A. R. Kuhns and A. M. Readel for their constructive criticism of a draft of this report.

Florence County lies in the Coastal Plain of South Carolina and has, to some degree, been overlooked for its amphibian and reptile diversity in comparison with the rest of the Coastal Plain. Only a handful of species have physical vouchers to document their occurrence in the county, and a number of common species have never been published. Searches of museum collections were performed via the HerpNet data portal, and additional universities were contacted for records. The species in the following list have never been published from Florence County; nevertheless, vouchers for these species do exist and are presented below. Museum acronyms follow Leviton et. al. (1985): *Ambystoma opacum* [MSU SH.4291], *Desmognathus auriculatus* [CU 5936; MSU HE.13479–85], *Eurycea cirrigera* [CU 5935], *Plethodon chlorobryonis* [USNM 463847–55], *Plestiodon* (*Eumeces*) *fasciatus* [CUSC 592; INHS 9063], *Plestiodon* (*Eumeces*) *laticeps* [INHS 9064], *Nerodia erythrogaster* [CUSC 381, 538], *Nerodia fasciata* [USNM 91416], *Kinosternon subrubrum* [INHS 9062], and *Sternotherus odoratus* [CUSC 115]. The only published record that could be found was for *Masticophis flagellum* (Camper and Brooks 2005).

The majority of aforementioned specimens were collected in or before 1971; however, Erskine College Vertebrate Collection (ECVC) contains recent (≤ 5 years) vouchers of most of these species for Florence County, documenting their continued occurrence in this area, as well as new records. New county records are presented below. Many of these species are commonly encountered in the county; we simply provide a voucher specimen for documentation of its occurrence. Geocoordinates are based on datum WGS 84. Scientific and English names follow Crother (2008) and all species identifications (physical and photo vouchers) were verified by Mary Lang Edwards unless otherwise stated. All specimens and photographs are deposited in the ECVC and Photo Voucher Collection (ECPVC) in Abbeville County, South Carolina.

Caudata — Salamanders

Siren intermedia (Lesser Siren). S. Cartersville Hwy., Timmonsville. 34.2764ºN, 79.5891ºW. 15 September 2005. J. Broach. ECVC 229. Taken from temporary pool of water branching off of a swamp area.

Anura — Frogs

Anaxyrus terrestris (Southern Toad). S. Cartersville Hwy., Timmonsville. 34.2240ºN, 79.5752ºW. 26 August 2006. C. McMahan and J. Broach. ECVC 314. Collected at night among debris alongside of pond. Numerous individuals were out. The most commonly encountered toad of the area.

Gastrophryne carolinensis (Eastern Narrow-mouthed Toad). S. Cartersville Hwy., Timmonsville. 34.2247ºN, 79.5752ºW. 15 April 2006. C. McMahan, J. Broach, and J. Wicker. ECVC 270. Found under rock in middle of dirt trail at night.

Hyla chrysoscelis (Cope's Gray Treefrog). S. Cartersville Hwy., Timmonsville. 34.1447ºN, 78.5813ºW. 24 June 2007. J. Broach. ECVC 624. Found at night along edge of puddle after late rain in afternoon.

Hyla cinerea (Green Treefrog). Twin Bridge Rd., Timmonsville. 34.3319º N, 79.5548ºW. 16 July 2007. J. Broach. ECVC 588. Collected on rainy night crossing road near Sparrow Swamp.

Hyla femoralis (Pine Woods Treefrog). Young Rd., Timmonsville. 34.3527ºN, 79.5572ºW. 16 July 2007. J. Broach. ECVC 587. Collected during rainy night 100 m from intersection with S. Hill Rd.

Hyla squirella (Squirrel Treefrog). S. Cartersville Hwy., Timmonsville. 34.2314ºN, 79.5753ºW. 26 August 2006. C. McMahan and J. Broach. ECVC 335. Found at night on side of building. Numerous individuals of this species were found on sides of buildings near lights.

Lithobates catesbeianus (American Bullfrog). S. Cartersville Hwy., Timmonsville. 34.2240ºN, 79.5752ºW. 24 June 2007. J. Broach and J. Wicker. ECVC 591. Caught along edge of a fish pond during day.

Lithobates clamitans (Green Frog). S. Cartersville Hwy., Timmonsville. 34.2240ºN, 79.5752ºW. 26 August 2006. C. McMahan and J. Broach. ECVC 334. Collected at night alongside edge of pond.

Lithobates sphenocephalus (Southern Leopard Frog). S. Cartersville Hwy., Timmonsville. 34.1424ºN, 79.5813ºW. 03 June 2007. J. Broach. ECVC 593. Collected at night alongside Lynches River. Found in tall grasses and shrubs along river edge.

Scaphiopus holbrookii (Eastern Spadefoot Toad). S. Cartersville Hwy., Timmonsville. 34.2954ºN, 79.5758ºW. 23 March 2007. C. McMahan, J. Broach, J. Gladden, J. Durham, D. Camak, and J. Wicker. ECVC 442. Collected while crossing small wooded path at night after heavy rain. Several individuals were observed along side of and on path.

Testudines — Turtles

Clemmys guttata (Spotted Turtle). S. Cartersville Hwy., Timmonsville. 34.1575ºN, 79.5843ºW. 06 April 2007. J. Broach and C. McMahan. ECPVC 008. Found alongside of water-edge in swamp habitat.

Squamata — Lizards

Aspidoscelis sexlineata (Six-lined Racerunner). S. Cartersville Hwy., Timmonsville. 34.2126ºN, 79.5757ºW. 10 June 2007. J. Broach. ECVC 585. Caught while running to shrubs in an open field among a forested lot.

Sceloporus undulatus (Eastern Fence Lizard). S. Cartersville Hwy., Timmonsville. 34.2126ºN, 79.5757ºW. 14 June 2007. J. Broach. ECVC 584. Caught on pine tree along margin of a field.

Scincella lateralis (Little Brown Skink). S. Cartersville Hwy., Timmonsville. 34.2170ºN, 79.5754ºW. 25 September 2006. J. Broach, J. Wicker, and C. McMahan. ECVC 337. Found during the day under log in middle of grassy field near small growth of shrubs.

Squamata — Snakes

Agkistrodon contortrix (Copperhead). Second Loop Rd., Florence. 34.9583ºN, 79.4740ºW. 07 June 2007. J. Broach. ECVC 575. Caught in debris on lot being cleared for housing development.

Agkistrodon piscivorus (Cottonmouth). S. Cartersville Hwy., Timmonsville. 34.1526ºN, 79.5867ºW. 7 July 2006. J. Broach. ECVC 306. Found around base of tree in swamp.

Coluber constrictor (North American Racer). State Hwy. 403 ca. 100 m S of Timmons Rd., Timmonsville. 34.4308ºN, 79.5766ºW. 13 June 2007. J. Broach. ECVC 576. DOR.

Crotalus horridus (Timber Rattlesnake). Young Rd., Timmonsville. 34.3411ºN, 79.5520ºW. 31 July 2007. J. Broach. ECVC 634. DOR within 50 m of intersection with S. Hill Rd.

Farancia abacura (Red-bellied Mudsnake). S. Cartersville Hwy., Timmonsville. 34.1533ºN, 79.5865ºW. 04 June 2007. J. Broach. ECVC 636. Caught in late afternoon crossing dirt path after a brief rain.

Nerodia taxispilota (Brown Watersnake). Twin Bridge Rd., Timmonsville. 34.3339ºN, 79.5545ºW. 24 June 2007. J. Broach and J. Wicker. ECVC 626. Captured out of tree extending over water where Twin Bridge Rd. crosses Sparrow Swamp.

Pantherophis alleghaniensis (Eastern Ratsnake). Old Sansburry Rd., Timmonsville. 34.4102ºN, 79.5540ºW. 14 June 2007. J. Broach. ECVC 577. Found crossing road ca. 30 m from intersection with Young Rd.

Acknowledgments.—We thank Jena Gladden, Josh Wicker, Jessica Durham, and David Camak for their assistance in the field, as well as the Collections Management Staff at Erskine College (J. Gladden and D. Camak). We thank Mallory Eckstut and Ryan Chabarria for reviewing an earlier draft of this manuscript. Many thanks to Mary Lang Edwards for verifying specimen identifications.

Trauth et al. (2004) provided a much-needed summation of records on 59 species of amphibians and 78 species of reptiles in Arkansas. Since then, numerous individual as well as compilations of records have been documented for the state (Caldwell and Tumlison 2005; Robison and McAllister 2007b, 2008b). Here we provide eight additional geographic (new county) records for six amphibians (one salamander, five frogs) and two snakes from various sites in Arkansas. Specimens were verified by Stanley E. Trauth, and voucher specimens were deposited in the Arkansas State University Herpetological Museum (ASUMZ), State University, Arkansas. Current common names follow Crother (2008).

Caudata – Salamanders

Notophthalmus viridescens louisianensis (Central Newt). ARKANSAS CO.: Bayou Meto at St. Hwy. 152 (34.2107°N, 91.4224°W). 6 May 1976. M. Evans. ASUMZ 31224. New county record that partially fills a distributional gap between Lincoln (Robison and McAllister, 2008a) and Monroe counties.

Anura – Frogs

Hyla chrysoscelis/versicolor sibling species complex (Gray Treefrog). SEARCY CO.: Middle Fork Little Red River at US 65, S of Leslie (35.4927°N, 92.3312°W). 04 May 2002. H. W. Robison. ASUMZ 31230. New county record that fills a hiatus between Van Buren (Robison and McAllister 2007a) and Marion counties.

Hyla cinerea (Green Treefrog). SCOTT CO.: Waldron (34.5357°N, 94.0529°W). 15 April 1999. H. W. Robison. ASUMZ 31229. New county record. Fills a distributional gap in extreme west-central Arkansas among Polk and Sebastian counties.

Pseudacris crucifer (Spring Peeper). ARKANSAS CO.: De Witt (34.1729°N, 91.2013°W). 2 March 1978. M. Evans. ASUMZ 31228. New county record filling distributional gap between Desha and Lincoln counties.

Pseudacris fouquettei (Cajun Chorus Frog). JOHNSON CO.: Clarksville, 458 Co. Rd. 3411 (35.2954°N, 93.2957°W). 14 March 2008. T. Kremers. ASUMZ 31227. New county record filling a distributional gap in the Arkansas River valley between Franklin and Pope counties. This species, formerly known as *P. feriarum*, was recentlydescribed by Lemmon et al. (2008) with a range that includes all of Arkansas.

Lithobates (= *Rana*) *palustris* (Pickerel Frog). JOHNSON CO.: Clarksville, 458 Co. Rd. 3411 (35. 2954°N, 93.2957°W). 16 March 2008. ASUMZ 31225. LOGAN CO.: 1.6 km E Magazine on St. Hwy 10 (35.0959°N, 93.4746°W). 14 April 2007. D. Powell. ASUMZ 31226. New county records. Fills distributional gaps north and south of the Arkansas River valley, respectively.

Squamata — Snakes

Cemophora coccinea copei (Northern Scarletsnake). LAFAYETTE CO.: Stamps (33. 2134°N, 92.5234°W). 15 January 1974. B. Lindsay. ASUMZ 31231. New county record. This snake is sporadically distributed in Arkansas and we provide an additional record for the extreme part of the state adjacent to previous record in Columbia County.

Diadophis punctatus sticogenys (Mississippi Ring-necked Snake). LAFAYETTE CO.: Stamps (33.2134°N, 92.5234°W). 15 September 1986. B. Lindsay. ASUMZ 31232. New county record partially filling a distributional gap in the extreme southern tier of counties in the state.

Acknowledgments.—Many thanks to S. E. Trauth for curatorial assistance and specimen verification, and M. Evans, T. Kremers, B. Lindsay, and D. Powell for providing vouchers. Specimens were collected under the authority of Arkansas Scientific Collecting Permits issued to HWR by the Arkansas Game and Fish Commission.

Little attention has been paid to the herpetofauna of North Dakota beyond the publications of Wheeler and Wheeler (1966) and Jundt (2000). Field work conducted by us on three trips in 2008 yielded a number of new and updated county records for North Dakota. We felt it significant to include updated county records because the latest published record for any species we collected was 1977. Records were obtained by road cruising, search and seizure, and hoop trapping. To the best of our knowledge, the *Apalone spinifera* record represents the first specimen of this species from North Dakota to be deposited in an official collection or institution. Voucher specimens and photographic records were deposited in the James Ford Bell Museum of Natural History (JFBM). Specimen numbers preceded by the letter "P" are cataloged in the photo collection. All specimens and photos were verified by Kenneth Kozak and Ben Lowe. Geocoordinates are based on datum WGS 84. Field work was conducted under permit number GNF02465468.

Anura — Frogs

Anaxyrus (= Bufo) cognatus (Great Plains Toad). Barnes Co.: NW of Valley City (46.9823000°N, 98.0889500°W). 25 July 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P267. Foster Co.: Hwy 281 NW of Melville (47.4238800°N, 99.1386000°W). 25 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15862.

Anaxyrus (= Bufo) woodhousii (Woodhouse's Toad). McKenzie Co.: Theodore Roosevelt National Park, North Unit (47.6126600°N, 103.3768000°W). 30 August 2008. Updated county record. J. B. LeClere and C. E. Smith. JFBM P268.

Lithobates (= Rana) pipiens (Northern Leopard Frog). Barnes Co.: CR 19 NW of Valley City (46.9700900°N, 98.0470300°W). 25 July 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P280. Eddy Co.: CR 15 E of New Rockford (47.6870600°N, 98.7282400°W). 25 July 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15880. Logan Co.: CR 34 SW of Gackle (46.5293100°N, 99.2199800°W). 26 July 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P281. McIntosh Co.: Hwy 13 E of Wishek (46.2574500°N, 99.4243800°W). 26 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P282. Morton Co.: CR 1806 S of Bismarck (46.6913800°N, 100.8038600°W). 29 August 2008. Updated county record. J. B. LeClere and C. E. Smith. JFBM P272. Richland Co.: CR 11 W of Hankinson (46.0663600°N, 96.9984900°W). 27 July 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P283.

Lithobates (= Rana) sylvaticus (Wood Frog). Barnes Co.: 29th St. SE, NW of Valley City (46.9941200°N, 98.1179200°W). 25 July 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15881.

Spea bombifrons (Plains Spadefoot). Eddy Co.: 74th Ave NE, E of New Rockford (47.6592900°N, 98.9690600°W). 25 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15868.

Testudines — Turtles

Apalone spinifera (Spiny Softshell). Morton Co.: Tributary stream of the Missouri River S of Bismarck (46.6913600°N, 100.8039900°W). 31 August 2008. New county record and the first specimen of this species from North Dakota to be entered into a recognized collection. J. B. LeClere and C. E. Smith. JFBM 16054.

Chelydra serpentina (Snapping Turtle). Morton Co.: Tributary stream of the Missouri River S of Bismarck (46.6913900°N, 100.8038900°W). 31 August 2008. New county record. J. B. LeClere and C. E. Smith. JFBM P275.

Chrysemys picta (Painted Turtle). Eddy Co.: New Rockford (47.6853600°N, 99.1350600°W). 25 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P271. Logan Co.: Burnstad (46.3794400°N, 99.6191800°W). 26 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P270. McIntosh Co.: 26th Ave SE N of Zeeland (46.1133900°N, 99.8367600°W). 26 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 16052. Morton Co.: Tributary stream of the Missouri River S of Bismarck (46.6913900°N, 100.8038900°W). 29 August 2008. Updated county record. J. B. LeClere and C. E. Smith. JFBM P296. Richland Co.: Hwy 11 W of Lidgerwood (46.0787900°N, 97.2196700°W). 27 July 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P274. Sargent Co.: Hwy 11 NW of Rutland (46.0795700°N, 97.5853000°W). 27 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15865.

Graptemys pseudogeographica (False Map Turtle). Morton Co.: Tributary stream of the Missouri River S of Bismarck (46.6913900°N, 100.8038900°W). 31 August 2008. New county record. J. B. LeClere and C. E. Smith. JFBM P297.

Squamata — Snakes

Coluber constrictor (North American Racer). McKenzie Co.: Theodore Roosevelt National Park (47.5955900°N, 103.2826000°W). 30 August 2008. Updated county record. J. B. LeClere and C. E. Smith. JFBM 16055. Morton Co.: CR 84 N of Flasher (46.5836700°N, 101.2704800°W). 20 September 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P276.

Opheodrys vernalis (Smooth Greensnake). Billings Co.: Hwy 85 N of Fairfield (47.1985000°N, 103.2230700°W). 19 September 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P285. Eddy Co.: Hwy 20 N of McHenry (47.5954700°N, 98.5857700°W). 25 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15878. Foster Co.: Hwy 20 SE of McHenry (47.5612600°N, 98.5684000°W). 25 July 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15870. Logan Co.: Hwy 30 N of Lehr (46.3065300°N, 99.3513000°W). 27 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15875. McIntosh Co.: Hwy 13 W of Wishek (46.2591900°N, 99.5731400°W). 27 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15869. Morton Co.: I-94 NE of Glen Ullin (46.8636800°N, 101.6880400°W). 20 September 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 16056. Slope Co.: Hwy 85 NE of Amidon (46.5257000°N, 103.1961200°W). 20 September 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 16060.

Pituophis catenifer (Gophersnake). Billings Co.: Theodore Roosevelt National Park (46.9310900°N, 103.4318900°W). 19 September 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 16059. Grant Co.: Hwy 21 SW of Carson (46.4005700°N, 101.6002200°W). 20 September 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P286. Morton Co.: CR 1806 S of Bismarck (46.6952100°N, 100.8072400°W). 29 August 2008. Updated county record. J. B. LeClere and C. E. Smith. JFBM 16057. Stark Co.: Hwy 85 N of Belfield (46.9121400°N, 103.1897700°W). 30 August 2008. New county record. J. B. LeClere and C. E. Smith. JFBM P287.

Storeria occipitomaculata (Red-bellied Snake). Barnes Co.: CR 19 NW of Valley City (46.9888300°N, 98.0822300°W). 25 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P288. LaMoure Co.: Hwy 281 N of Nortonville (46.5887000°N, 98.7044700°W). 26 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15876. Logan Co.: CR 34 SE of Streeter (46.4567400°N, 99.3516100°W). 27 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15861. McIntosh Co.: Hwy 13 E of Wishek (46.2590000°N, 99.4892900°W). 27 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15872. Sargent Co.: CR 11 W of Cogswell (46.1097000°N, 97.9582200°W). 27 July 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15863.

Thamnophis radix (Plains Gartersnake). Barnes Co.: Hwy 22 E of Eckelson (47.6870300°N, 98.7762000°W). 25 July 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P289. Eddy Co.: CR 15 E of New Rockford (47.6873400°N, 99.0530800°W). 25 July 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15879. Foster Co.: Hwy 20 S of McHenry (47.5580400°N, 98.5651700°W). 25 July 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15864. Hettinger Co.: Mott (46.3737900°N, 102.3312100°W). 20 September 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P290. LaMoure Co.: Hwy 281 NE of Nortonville (46.5691700°N, 98.7044800°W). 26 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15873. Logan Co.: Hwy 34 SW of Gackle (46.5293300°N, 99.2058200°W). 26 July 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM P291. McIntosh Co.: Hwy 13 E of Wishek (46.2590000°N, 99.4829200°W). 27 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15871. Richland Co.: Hwy 11 W of Lidgerwood (46.0782600°N, 97.1611300°W). 27 July 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15867. Sargent Co.: Hwy 11 W of Cogswell (46.1097300°N, 97.9399900°W). 27 July 2008. New county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 15866.

Crotalus viridis (Prairie Rattlesnake). Billings Co.: NE of Medora (47.0513500°N, 103.3779000°W). 30 August 2008. Updated county record. J. B. LeClere and C. E. Smith. JFBM P278. Grant Co.: Hwy 21 W of Lark (46.4149100°N, 101.5500900°W). 20 September 2008. Updated county record. J. B. LeClere, C. E. Smith, and R. E. Blasus. JFBM 16062. McKenzie Co.: Theodore Roosevelt National Park (47.5927500°N, 103.3000700°W). 30 August 2008. Updated county record. J. B. LeClere and C. E. Smith. JFBM P279.

The recent publication of a thorough treatment of the herpetofauna of Georgia (Jensen et al. 2008) provides a basis for documenting new county records. Herein, we document new county records for Georgia amphibians and reptiles, provide voucher specimens for several counties lacking museum records, and provide a county record update. Unless otherwise noted,

all specimens were verified by Lance D. McBrayer and were deposited in the Georgia Southern University (GSU) collection, Statesboro, Georgia. New county records and county updates were determined by consulting Williamson and Moulis (1994) and Jensen et al. (2008). Records are the first for each county unless otherwise indicated. Geocoordinates are approximations derived from Google Earth.

Caudata — Salamanders

Ambystoma talpoideum (Mole Salamander). Camden Co.: 15.0 km ESE Woodbine (30.943056°N, 81.597222°W). 06 February 2008. J. G. Palis and D. Stevenson. Adult dipnetted from depressional wetland within mixed pine-oak hammock. GSU 20000. First museum voucher specimen for county (John B. Jensen, pers. comm., 2008)

Amphiuma means (Two-toed Amphiuma). Brooks Co.: 1.5 km NW Nankin in roadside swamp at State Hwy. 333 (30.673056°N, 83.478056°W). 26 June 2008. D. Stevenson. GSU 20001. Glynn Co.: 7.4 km SW Darien (31.333889°N, 81.513611°W). 3 March 2008. D. Stevenson. Mucky swamp south of the Altamaha River. GSU 20002.

Eurycea guttolineata (Three-lined Salamander). Ben Hill Co.: Mobley Bluff Road boat landing on the Ocmulgee River (31.774858°N, 83.00805°W). 17 November 2008. D. Stevenson. GSU 20050.

Eurycea quadridigitata (Dwarf Salamander). Appling Co.: 0.2 km NW Eason Bluff Landing in Altamaha River floodplain swamp (31.904444°N, 82.205°W). 04 July 2008. D. Stevenson. GSU 20003. First museum voucher specimen for county.

Notophthalmus perstriatus (Striped Newt). Camden Co.: 15.0 km ESE Woodbine (30.943056°N, 81.597222°W and 30.940833°N, 81.5975°W). 06 February 2008. J. G. Palis and D. Stevenson. Adults and larvae dipnetted from two depressional wetlands within mixed pine-oak hammock. GSU 20008 (photo). Only the second record for the county for this state-listed (Threatened) species, and the first record for the county since 1953. Extends range ca. 8.0 km closer to the Georgia coast.

Notophthalmus viridescens (Eastern Newt). Brooks Co.: 1.5 km NW Nankin in roadside swamp at State Hwy. 333 (30.673056°N, 83.478056°W). 26 June 2008. D. Stevenson; depressional wetland adjacent to and E of State Hwy. 333, 0.3 km S of jct. with Cty. Rte. 100 (30.7075°N, 83.506111°W). 26 June 2008. D. Stevenson. GSU 20004–06. First museum voucher specimens for county. Camden Co.: 15.0 km ESE Woodbine (30.943056°N, 81.597222°W). 06 February 2008. D. Stevenson and J. G. Palis. Adult dipnetted from depressional wetland within mixed pine-oak hammock. GSU 20007. Wheeler Co.: 5.6 km E of State Hwy. 19 on Cty. Rte. 95 (31.972947°N, 82.578653°W). 19 January 2009. D. Stevenson. Adult dipnetted from roadside wetland. GSU 20051.

Pseudotriton montanus (Mud Salamander). Glynn Co.: 7.4 km SW Darien (31.333889°N, 81.513611°W). 03 March 2008. D. Stevenson. Adult from under log in mucky swamp S of the Altamaha River. GSU 20009.

Siren intermedia (Lesser Siren). Appling Co.: 0.2 km NW Eason Bluff Landing in Altamaha River floodplain swamp (31.904444°N, 82.205°W). 04 July 2008. D. Stevenson. GSU 20010.

Siren lacertina (Greater Siren). Wayne Co.: 1.9 km N of Brantley County line on State Hwy. 301 (31.362778°N, 81.946111°W). 11 March 2008. D. Stevenson. Adult dropped by Great Blue Heron (*Ardea herodias*) at edge of deep, vegetated ditch adjacent to the W side of State Hwy. 301. GSU 20011.

Anura — Frogs

Acris crepitans (Northern Cricket Frog). Tattnall Co.: 19.7 km S Reidsville; county boat landing on the E side of the Ohoopee River at its confluence with the Altamaha River (31.896667°N, 82.109167°W). 02 May 2008. D. Stevenson. GSU 20014. Wheeler Co.: 3.0 km E Lumber City; Little Ocmulgee River at State Hwy. 19 (31.935278°N, 82.670556°W). 02 May 2008. D. Stevenson. GSU 20012–13.

Hyla gratiosa (Barking Treefrog). Brooks Co.: 0.3 km S of jct. with County Rte.100; depressional wetland adjacent to and E of State Hwy. 333 (30.7075°N, 83.506111°W). 26 June 2008. D. Stevenson. Tadpoles dipnetted from isolated depressional wetland. GSU 20017; Coffee Co.: Broxton Rocks Natural Area Preserve (31.733611°N, 82.8625°W). 06 July 2008. D. Stevenson, F. Snow, and B. Brody. Recent metamorph dipnetted from borrow pit. GSU 20018.

Lithobates capito (Gopher Frog). Camden Co.: 18.0 km ESE Woodbine (30.940833°N, 81.581111°W). 13 February 2008. D. Stevenson and J. G. Palis. Adult captured in a funnel trap placed at the entrance to a Gopher Tortoise (*Gopherus polyphemus*) burrow in sandhill habitat. GSU 20015 (photo); Wheeler Co.: 4.6 km NNE Lumber City (31.965278°N, 82.683611°W). 21 March 2008. J. Jensen and D. Stevenson. Adult observed in Gopher Tortoise (*Gopherus polyphemus*) burrow in xeric sandhill habitat. Verified by L. McGee. GMNH 50093 (photo).

Pseudacris ocularis (Little Grass Frog). Baker Co.: 12 km SW Newton, Joseph W. Jones Ecological Research Center at Ichauway (31.248889°N, 84.495278°W). 16 April 2004. G. Miller. Adult caught at drift fence encircling seasonal pond. GSU 20043.

Testudines — Turtles

Apalone spinifera (Spiny Softshell). Ben Hill Co.: Mobley Bluff Road boat landing on the Ocmulgee River (31.7751°N, 83.007956°W). 17 November 2008. D. Stevenson. GSU 20052. Telfair Co.: Altamaha River at Horse Creek Wildlife Management Area (31.815278°N, 82.839444°W). 17 August 2008. D. Stevenson. GSU 20042. Toombs Co.: 10.7 km SE Uvalda; Gray's Landing at the Altamaha River (31.966389°N, 82.428889°W). 02 May 2008. D. Stevenson. GSU 20019.

Clemmys guttata (Spotted Turtle). Brantley Co.: State Hwy. 32 at Needmore (31.333333°N, 81.903889°W). 21 May 2000. A. Walde. Adult found in blackwater creek swamp near State Hwy. 32. GSU 20021 (photo). Glynn Co.: 6.4 km SW Darien (31.346667°N, 81.510833°W). 03 April 2008. D. Stevenson and E. Grunwald. Adult male found in freshwater swamp. GSU 20020 (photo).

Deirochelys reticularia (Chicken Turtle). Toombs Co.: 1.8 km W of Tattnall County line on County Rte. 188 (31.953333°N, 82.231667°W). 15 March 2008. D. Stevenson and B. Willis-Stevenson. Adult female found AOR. Verified by L. McGee. GMNH 50096 (photo).

Kinosternon baurii (Striped Mud Turtle). Long Co.: 21.1 km WNW Ludowici (31.785833°N, 81.9475°W). 28 February 1998. R.A. Moulis and J.B. Blue, Jr. Adult captured in cypress pond wetland in sandhills. GSU 98.0548. First museum voucher specimen for county.

Pseudemys concinna floridana (Coastal Plain Cooter). Toombs Co.: State Hwy. 147 at Zigman Whonic Rd. (31.972503°N, 82.295192°W). 15 October 2008. D. Stevenson. Subadult DOR at beaver (*Castor canadensis*) pond wetland. GSU 20053.

Trachemys scripta (Pond Slider). Appling Co.: 4.5 km NW Davis on Moody Forest Natural Area Preserve (31.930833°N, 82.283333°W); 04 July 2008. D. Stevenson. GSU 20023 (photo). Jeff Davis Co.: Hazlehurst, Hollingsworth Blvd. at railroad tracks (31.86033°N, 82.589722°W). 21 June 2008. D. Stevenson. Adult found DOR. GSU 20024.

Squamata — Lizards

Anolis carolinensis (Green Anole). Telfair Co.: 16.0 km SW Lumber City, Mopani Preserve; N shore of the Ocmulgee River. (31.845756°N, 82.792647°W). 02 December 2008. D. Stevenson. GSU 20054.

Aspidoscelis (= *Cnemidophorus*) *sexlineatus* (Six-lined Racerunner). Wayne Co.: 7.4 km N Mt. Pleasant; Sansavilla Bluff at Altamaha River; Sansavilla Wildlife Management Area (31.494444°N, 81.647778°W). 03 July 2008. D. Stevenson. GSU 20044 (photo).

Ophisaurus attenuatus (Slender Glass Lizard). Elbert Co.: 5.5 km E Bell on River Road (33.993333°N, 82.715278°W). 31 May 2008. J. Oguni. GSU 20025 (photo).

Squamata — Serpentes

Agkistrodon contortrix (Copperhead). Bulloch Co: County Rte. 364 (Old River Road), 2.9 km NW of jct. with State Hwy. 24-W (32.5075°N, 81.650833°W). 23 March 1995. R. A. Moulis and G. K. Williamson. GSU 98.0980.

Cemophora coccinea (Scarletsnake). Wayne Co.: 7.6 km E Gardi; Penholoway Swamp Wildlife Management Area (31.549167°N, 81.714722°W). 05 July 2008. D. Stevenson and M. Wallace. Dug from six-lined racerunner (*Aspidoscelis* (*Cnemidophorus*) *sexlineatus*) burrow system in sandy soil. GSU 20026.

Coluber (=*Masticophis*) *flagellum* (Coachwhip). Brooks Co.: 5.8 km E Nankin (Nankin Road at jct. with Cty. Rte. 83) (30.670833°N, 83.399167°W). 22 June 2008. D. Stevenson. Adult found DOR. GSU 20029. Irwin Co.: 15.8 km SW Ocilla, Alapaha River sandhill located S of State Hwy. 319 (31.525128°N, 83.364961°W). 31 October 2008. A. Safer and D. Stevenson. Juvenile found at Gopher Tortoise (*Gopherus polyphemus*) burrow. GSU 20056 (photo).

Crotalus horridus (Timber Rattlesnake). Dade Co.: 3.5 km SE of U.S. Hwy. 11/58 on State Hwy. 136 (34.8475°N, 85.499444°W). 21 July 2002. J. G. Palis. Adult male found DOR. Verified by L. White. SIUC R03454. First museum voucher specimen for county. Tattnall Co.: Baxter Durrence Road at Mushmelon Creek (9.2 km SSW Glennville, by air). Adult DOR (31.864556°N, 81.965542°W). 26 October 2008. D. Stevenson and B. Willis-Stevenson. GSU 20055. White Co.: Chattahoochee National Forest at State Hwy. 348 (34.724722°N, 83.842222°W). 22 August 2008. D. Stevenson and B. Willis-Stevenson. GSU 20045 (photo).

Farancia abacura (Red-bellied Mudsnake). Toombs Co.: 0.2 km S of State Hwy. 147 on Laura Dixon Road (31.978889°N, 82.276944°W). 17 August 2008. D. Stevenson. Adult found DOR. GSU 20046. Wheeler Co.: 0.5 km S of County Rte. 68 on State Hwy. 126 (32.110278°N, 82.691389°W). 10 June 2008. D. Stevenson. DOR adult male. GSU 20027.

Lampropeltis triangulum elapsoides (Scarlet Kingsnake). Baker Co.: 12 km SW Newton, Joseph W. Jones Ecological Research Center at Ichauway (31.284722°N, 84.471944°W). 25 April 2007. A. Heupel. Adult female caught in snake trap. GSU 20047 (photo). Burke Co.: 9.7 km E Girard. (33.052778°N, 81.612778°W). 13 April 2007. R. Redmond, M. Wallace, and D. Stevenson. GSU 20028 (photo).

Micrurus fulvius (Harlequin Coralsnake). Bacon Co.: Alma, near Hurricane Creek (31.594306°N, 82.485047°W). 23 May 2008. D. Deen. Adult. GSU 20057.

Nerodia erythrogaster (Plain-bellied Watersnake). Toombs Co.: Old River Road at Larry Dickerson Road (31.984167°N, 82.436389°W). 17 August 2008. D. Stevenson. Adult found DOR. GSU 20048. Wayne Co.: Doctortown, Jaycee's boat landing; floodplain forest adjacent to the Altamaha River (31.666667°N, 81.846389°W). 03 May 2008. D. Stevenson and D. Beamer. GSU 20030.

Nerodia taxispilota (Brown Watersnake). Coffee Co.: 9.2 km NE Relee; Flat Tub Wildlife Management Area (31.801667°N, 82.838889°W). 06 July 2008. D. Stevenson, F. Snow, and B. Brody. Juvenile found in river swamp. GSU20031.

Pituophis melanoleucus (Pine Snake). Brantley Co.: State Hwy. 32 at Popwellville (31.315833°N, 81.744444°W). 21 May 2000. A. Walde. Adult found AOR. GSU 20032 (photo). Wayne Co.: Madray Springs: on State Hwy. 169 at mile marker 14 within city limits (31.733503°N, 81.978233°W). 30 March 1997. J. Blue. DOR subadult. GSU 97.0085.

Storeria occipitomaculata (Red-bellied Snake). Baker Co.: 12 km SW Newton, Joseph W. Jones Ecological Research Center at Ichauway (30.191667°N, 84.483333°W). 24 October 2002. D. Temple. Adult dead on farm road. GSU 20049.

Virginia striatula (Rough Earthsnake). Appling Co.: 5.5 km NW Davis on Moody Forest Natural Area Preserve (31.940556°N, 82.2925°W). 30 March 2008. D. Stevenson and B. Cash. Adult under debris in floodplain forest along the Altamaha River. GSU 20033.

Acknowledgments.—We thank Lance D. McBrayer for verifying identification of specimens. We thank John B. Jensen for his generous help and for reviewing this article.

The state of Western Australia, encompassing a third of continental Australia, has a human population largely concentrated around the southwestern fringe, and that same area represents two adjacent biogeographic and climatic zones, the South-Western and Eucla Divisions, regions extensively used by the late Glen Storr in his numerous taxonomic studies of the Western Australian herpetofauna (e.g., Storr 1974). Although there are already several guides to the Western Australian herpetofauna, including the taxon-based guides to the entire state produced by the Western Australian Museum (Storr et al. 1983, 1990, 1999, 2002; Tyler et al. 2000) and a regional guide to the capital city, Perth (Bush et al. 1995), there has been no comprehensive guide to the southwest in its entirety. But is this any more than just a regionally much expanded version of the previous Perth field guide by the same authors and publisher? It is indeed.

The core of the book (Section Four, Frogs, and Section Five, Reptiles) is the usual series of colour photos, distribution maps/statements and listings of diagnostic characters, as in most modern field identification guides. But the authors have gone beyond this in trying to enthuse their audience, with numerous personal stories of catching reptiles and amphibians in the south-west. These are provided firstly as a series of tales of field trips to particular habitats, liberally illustrated with photographs, that constitute Section Three of the book ("In the Bush" [for non-Australian readers, the "Bush" is the Australian vernacular for the non-urban parts of the continent]), and which in other field guides would take the less entertaining form of photographs and descriptions of habitat types. Secondly, there are more specific notes accompanying the photographs in the identification section, detailing how the photographed individuals were found (e.g., p. 126, "headtorched on wattle tree at Ellenbrook"; p. 163, "raked from leaf litter on coastal dune at False Entrance Well"; p. 168, "found under piece of old iron in banksia woodland at Waterman"; p. 255, "found basking outside rabbit burrow on Lort River Station"). There are also tales of recent Australian herpetological history, such as the rediscovery of the skink *Tiliqua adelaidensis* (p. 20), the discovery of the frog *Spicospina flammocaerulea* (p. 94), the search for a potential new species of the skink genus *Glaphyromorphus* (p. 198), and the search for extant south-western populations of the python *Aspidites ramsayi* (p. 237), all emphasizing the thrill of exploration and discovery. All of this, together with an engaging writing style and a vast number of color photographs (there are few pages without at least one photograph of animals or people in the field) gives this book a unique flavor, guaranteed to entertain as well as educate an audience that potentially ranges from the member of the general public, through the keen amateur, to the professional herpetologist seeking to explore a new fauna.

The book opens with a map of the region covered (from Shark Bay on the west coast, in a sweeping arc to Eucla at the South Australian border on the south coast), with many of the localities mentioned later in the text labelled, as well as the major settlements for orientation. Section One (26 pages) provides general information on a wide range of topics, with recommendations on how to use the book, the basics of nomenclature and taxonomic method, methods for recognizing the presence of amphibians and reptiles, amphibian declines, a brief personal view of the inadequacies of wildlife conservation, the importance of taking field notes, methods of handling, transporting, and preserving amphibians and reptiles, the value of examining roadkilled reptiles, photography, dealing with problem snakes in urban environments, and insular populations. Section Two (13 pages) describes methods of locating and catching amphibians and reptiles, including triangulating calls, raking leaf litter and loose soil, turning rocks and logs, "fishing" for active lizards with insects, noosing fast-moving or wary lizards, headtorching and spotlighting, pit-trapping, and temporarily fencing around the spikey spinifex (*Triodia*) clumps that are so widespread in arid Australia (and home to so many reptiles). The habitat/field trip accounts of Section Three (27 pages) cover six areas: the dry stony habitats of the Murchison in the north-west, the swamps and forests of the far south-west, the degraded, now-fragmentary woodlands and granite outcrops of the Wheat Belt, the heathlands of the west coastal plain, the mining country and woodlands of the Eastern Goldfields, and the chenopod steppes of the Nullarbor Plain in the east. My only significant concern with these preliminary parts of the book is the lack of emphasis on the legal requirements needed to permit the activities the authors so enthusiastically espouse. It is only a single paragraph on page 16 that notes the need to obtain a permit from the Western Australian Department of Environment and Conservation before any of the activities in the book can be carried out.

The next two sections, the identification core, consist of brief accounts arranged taxonomically by class, family, genus and species/subspecies. Each species/subspecies account provides a common name (largely based on those coined by Ehmann [1992], though not always), taxonomic name, a brief diagnostic statement noting features to differentiate the species from similar species (many illustrated in the accompanying photographs, or in a few cases with line drawings), a verbal description of the call (for frogs), a size measurement, and a statement of distribution and habitat. Each species account is illustrated by one or more color photographs, almost all of high quality, though mostly small (54 mm wide), and a very small map identifying the overall range of

the species in Western Australia. Although small, the use of color and arrows on the maps, the latter highlighting tiny patches of distribution, makes the distribution readily recognizable. There are no keys. While some would argue that this decreases the value of the book, keys for the same fauna are available in the Western Australian Museum field guide series, and non-professionals rarely use them anyway (or if they do, they often misuse them). The identification format in this book is useful once the reader has got a rough match from the photos, but offers little help in getting to the right photo to start the process, other than flicking through the 197 pages of species accounts. This still results in the physical separation of the superficially similar and confusing pygopod lizards (pp. 129–142) and snakes (pp. 226–268), and separates the numerous small brown skinks into generic groupings arranged alphabetically (although at least the alphabet kept the elongate burrowing skinks of the genera *Hemiergis* and *Lerista* adjacent). The diagnostic statements (except for monotypic genera) are mostly only useful in differentiating between congeners. But having reached the correct genus, I found the diagnostic statements usually worked effectively (noticeable exceptions were the diagnostic statements for *Ctenotus pantherinus pantherinus*: "As for Eastern Leopard Skink" [*Ctenotus pantherinus ocellifer*], and *Ctenotus euclae*: "As for Centralian Wedge-snout Ctenotus" [*Ctenotus brooksi*]). I did not find any obvious errors in photographic identifications, although the photograph of the "yellow-eyed" *Strophurus spinigerus spinigerus* did not show an eye noticeably different from that of the "orange-eyed" *Strophurus spinigerus inornatus*.

The identification section terminates in a brief general account of marine reptiles that might be encountered as beach strandings. Atypically, this is not arranged by species and lacks identification aids, although two species of turtle and three of sea snakes are photographed.

The book closes with first aid treatment for snake bite (pp. 274–275), then a series of lists, first (pp. 276–282) species lists by island or archipelago (the southwest coastline has large numbers of continental islands), including references to the literature on each island, then mainland bioregion listings for each species (pp. 283–292), and finally a brief list of other general herpetological books and websites that may be of interest to readers ("Useful Books"). The index is brief and largely designed to locate only photographs, species accounts and broader topics. It certainly does not provide every citation of a species in the text.

Although a paperback, the production values are good. The book is printed on quality glossy paper, the binding is robust, both stitched signatures and glued, and the cover protected by a thick clear plastic protector, all of which facilitate the intended use of this book in a field setting.

Apart from the few criticisms noted, this book is a worthwhile and unique addition to the plethora of Australian herpetological field guides, and entertaining reading for those yearning for fieldwork in the southwest.

The British have somehow long been able to achieve something that has eluded television in most other countries: quality programming. Perhaps the best examples of this are provided by BBC nature documentaries, some accompanied by a book providing more details for those wanting to delve further. With exquisite photography and an attention to detail, those associated with David Attenborough have for decades been the gold standard in the field. As a result, our expectations from their newest offering, *Life in Cold Blood*, were high. Both the video (two DVDs containing five, 50-minute episodes) and the book (some 280 pages, plus an index of common and scientific names) generally met our expectations.

The book offers a nice balance of pictures and text. It reads like

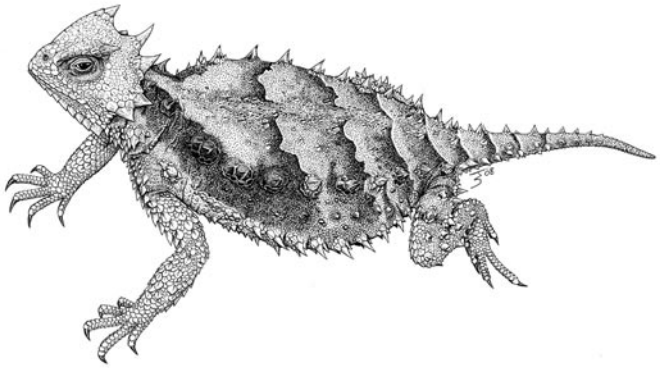
a large-scale overview of the diversity of herpetofauna, presented in four taxonomic chapters: amphibians; turtles and tortoises; crocodilians; and lizards and snakes. It concludes with a final chapter discussing ectothermic life as a whole. The video follows a similar organization. Drawing from decades of personal observation and study, Attenborough attempts to demonstrate the sophistication these groups evolved to fill seemingly every available niche. Topics ranging from life history and evolutionary theories to foraging and reproductive strategies are addressed through detailed accounts of example species, illustrated with brilliant photos or scintillating video. Several major themes run through the series: the dependence of amphibians and reptiles on outside temperature; the move from the water to progressively drier land, providing an illustration of the evolutionary process without being pushy; conservation, especially of amphibians; and the complexity of behaviors and adaptations shown by creatures that most consider primitive, such as parental behavior and pairing for life. The inclusion of the Panamanian golden frog (*Atelopus zetecki*), which went extinct in the wild during the production period, effectively drives the point home. The latter is interwoven throughout the series, but is inserted with a light touch, so that the message is one of wonder, rather than gloom-and-doom. This is enhanced by Mr. Attenborough, who is often openly delighted by what he reports. Delightfully, and unlike the new breed of television nature show hosts, the show isn't about him; Attenborough's presence and verbiage is not testosterone laden and overbearing, but rather informative and enlightening.

As products aimed at the non-specialist, both the book and the video do a superb job. Instead of being bogged down by scientific jargon, the average reader will easily follow the text. The numerous photos, many taken from the DVDs, provide for entertaining pauses along the way. The videography tends to be excellent. Some shots are taken inside nests and burrows, showing hatching behavior and other events that we have never seen displayed in this way before. Segments shot using infrared cameras offer enlightening views into nighttime activity and other events that transpire in the dark. Thermal imaging helps illustrate some points about the thermal relations of various species. Novel behavioral observations abound, and many can be witnessed first-hand in the DVDs. Attenborough gently and without preaching tells the stories of numerous species, engaging the lay person in the life of a creature they may have never heard of before, or even previously thought of as "gross" or "frightening." The flowery language and repeated projections of human characteristics may irritate the scientist. For example, an Australian sleepy lizard remaining by a mate that has been run over by a car is said in the video to be "grieving." Professional herpetologists may find statements such as "lizards, with their watertight skins, are immune to" dehydration when swimming in sea-water (p. 146) overly simplistic, but will still learn a fact or two about an unfamiliar species.

Although the book offers more detail, the video provides more pizzazz. It also offers something new: each episode is followed by a ten-minute "under the skin" section which offers much more than the "making of" segment promised on the dust jacket. As in his previous shows, Attenborough does not share the screen with other humans in this series. In these little snippets, however, the viewer is introduced to some of the scientists who aided in the research and filming, and gives a sense of the process of science and how long acquiring knowledge can take. This adds a dimension that is extremely valuable for those intending to use these videos in teaching. In addition, it is in these segments that conservation issues are often most directly addressed. Over the course of a week, we showed the DVDs to a group of about twenty people, ranging in age from four to 84 and in experience from none to retired biology professors. Every single viewer, regardless of age or experience level, learned new things. The show was a bit much for the younger children, and probably is most appropriate for those over 8. However, the feedback we received was enthusiastic. Younger viewers mostly liked the more dramatic scenes, such as a constrictor struggling to swallow a large deer. Older spectators noted the color quality, cinematography, and engaging delivery. Several said they were going to buy the series for home. Their only complaint was minor: Madagascan chameleons showed up in too many episodes. Our complaints are likewise few, and may be of little concern for most viewers. The first episode spends some time on digitally-created dinosaurs, something we could have done without.

Sir David Attenborough and the BBC have once again succeeded in taking a substantial academic subject and making it approachable to the general populace, while reminding scientists why they chose their careers in the first place. Aside from being an enjoyable experience for anyone interested in nature, *Life in Cold Blood* can provide discussion material for high school level biology or even a college-level animal behavior course. Public outreach programs can utilize the strong conservation message from this series to inspire interest in herpetological conservation from the general public as well. Though not really suited to the professional herpetologist as a reference book, the book may inspire future herpetologists as it provides wonderful insights into the lives of these fascinating creatures.

This year marks the 200th birthday of Charles Darwin and the 150th anniversary of the publication of his *Origin of Species* – perhaps the most influential biology book ever published. Amazingly, even as the scientific community has embraced the concept of evolution as the core of biology, the public in some countries has remained intractable. Less than half of Britons surveyed recently agree that evolution is the best explanation for the development of life (Williams 2006), and a British government report indicates that teachers there tend to avoid controversial topics such as the Crusades and Holocaust for fear of offending students (Vasagar 2007). In the US, many high-school biology teachers avoid the topic of evolution or downplay it because of public pressure, personal belief, or lack of sufficient exposure to the topic in college (Berkman et al. 2008). Polls consistently show that more Americans believe that human were created in their present form within the last 10,000 years than are comfortable with the idea that we slowly evolved from less advanced forms of life. Clearly, we are doing a poor job of reaching even our biology teachers, let alone our general public. Against this background, it is a pleasure to see a new product that is aimed at the general public, focuses on herpetology, and provides a matter-of-factly evolutionary perspective without being technical, boring, or preachy.



This is manuscript T-9-1158 of the College of Agricultural Sciences and Natural Resources, Texas Tech University.

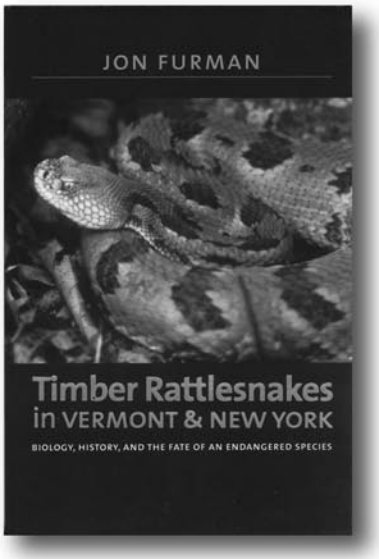
SNAKES
Ecology and Conservation
EDITED BY
STEPHEN J. MULLIN AND
RICHARD A. SEIGEL

"Yet another authoritative and cutting-edge volume on the biology of snakes, organized and written with the same attention to detail and scientific accuracy as its predecessors, *Snakes: Ecology and Evolutionary Biology* and *Snakes: Ecology and Behavior.* Add this alongside them on your library bookshelf; it is an essential tome for all researchers interested in serpents."



—JOSEPH T. COLLINS, THE UNIVERSITY OF KANSAS

The Troubled Story of the Fate of the Timber Rattler in the Northeast

Timber Rattlesnakes in Vermont & New York
Biology, History, and the Fate of an Endangered Species

Jon Furman

Timber Rattlesnakes, sometimes called border rattlers, are found in Vermont's Rutland County, and Warren, Washington, and Essex counties in New York. Despite their protective camoflauged skin, these snakes are endangered due to a long period of bounty hunting. *Timber Rattlesnakes in Vermont & New York* delves into the biology of the Timber Rattlesnake, man's relationship with this species in the northeast going back to the pre-Colonial era, what's being done in Vermont and New York to help these much maligned and misunderstood creatures from falling into extinction, and what the future may hold for these snakes.

"This is a well written interesting treatise on the timber rattlesnake bounty system in the Northeast. It includes good summaries of the life history of the snake, its bite and the treatment for it, and the effects of bounties on the populations of the reptile. I highly recommend it to persons interested in the snake and conservation of Northeast wildlife in general."
—Carl Ernst, Division of Amphibians and Reptiles, Smithsonian Institution

"This book will be an important contribution outlining the regional evolution of social and political attitudes involving changes that may, or may not, come just in time to save these magnificent animals."
—James H. Harding, Michigan State University Museum

Announcing a new book devoted to lizards... **Only $24.95!**

Lizards of the American Southwest *A Photographic Field Guide*

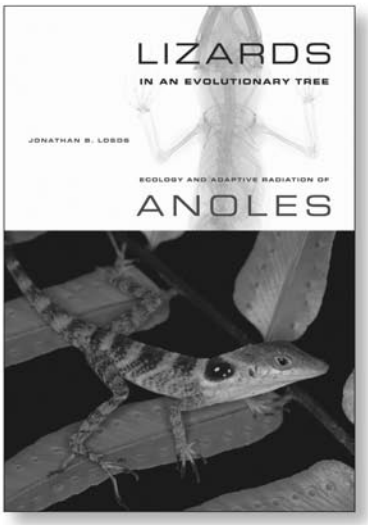
Lawrence L. C. Jones and Robert E. Lovich, eds.

Contributors: 77 contributors, including 63 authors, all qualified taxa experts, and many world-class photographers. Forward by Laurie Vitt.

Scope: Covers all 96 native species of AZ, CA, CO, NM, NV, TX (W of Pecos River), and UT, with chapters on adjacent Mexican states.

Species Accounts: Each account has information on identification, similar species, habitats, natural history, taxonomy, subspecies and variation, range, and viewing tips.

Other Sections: Numerous sections devoted to lizards include life history, behavior, non-native species, conservation and ethics, taxonomy and nomenclature, observing lizards, and lizards of northwestern Mexico.



Photographs: For most species there are high-resolution color photographs of adult males, females, and juveniles.

Specifications: 6 x 9 inch paperback, 568 pages, 470 color photographs, range maps, and line drawings. **ISBN 978-1-933855-35-6**

100% of the Royalties go to a grant program to support research on reptiles in the American Southwest

Rio Nuevo Publishers, Tucson, Arizona. Order online at www.treasurechestbooks.com and receive a 20% discount. Anticipated release date is July 2009.

Lizards & Monsters

Lizards in an Evolutionary Tree

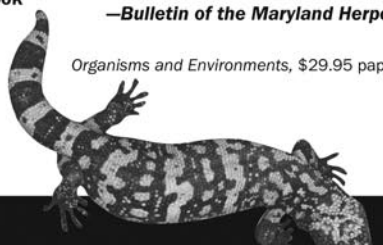
Ecology and Adaptive Radiation of Anoles

JONATHAN B. LOSOS
Foreword by Harry W. Greene

"In a book both beautifully illustrated and deeply informative, Losos...celebrates and analyzes the diversity of the natural world that the fascinating anoline lizards epitomize."

—Douglas J. Futuyma, State University of New York, Stony Brook

Organisms and Environments, $75.00 cloth



Biology of Gila Monsters and Beaded Lizards

DANIEL D. BECK
With Contributions from Brent E. Martin and Charles H. Lowe
Photographs by Thomas Wiewandt
Foreword by Harry W. Greene

New in Paperback—"This book will hold your interest from the moment you pick it up! We highly recommend it and feel that every herpetologist will want a copy of this opus on our only poisonous lizards."

—Bulletin of the Maryland Herpetological Society

Organisms and Environments, $29.95 paper

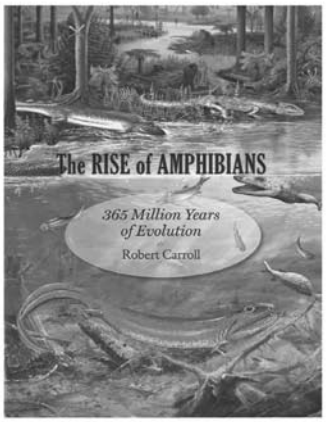
UNIVERSITY OF CALIFORNIA PRESS

TURTLES OF THE UNITED STATES AND CANADA

second edition

Carl H. Ernst and Jeffrey E. Lovich

From diminutive mud turtles to giant alligator snappers, two of North America's most prominent experts describe the turtles that live in the fresh, brackish, and marine waters north of Mexico. Incorporating the explosion of new scientific information published on turtles over the past fifteen years—including the identification of four new species—Ernst and Lovich supply comprehensive coverage of all fifty-eight species, with discussions of conservation status and recovery efforts.



"[A] monumental work . . . the standard reference to North American turtles for the next generation of biologists. Every serious vertebrate biologist on the continent will want a copy."
—*Herpetological Review*, reviewing the first edition

$85.00 hardcover

THE RISE OF AMPHIBIANS

365 Million Years of Evolution

Robert Carroll

In this landmark publication, one of the leading paleontologists of our time explores a pivotal moment in vertebrate evolution, the rise of amphibians. Synthesizing findings from the rich and highly diverse fossil record of amphibians, Carroll traces their origin back 365 million years. *The Rise of Amphibians* is documented with more than two hundred illustrations of fossil amphibians and sixteen color plates.

"An excellent, comprehensive overview of the diversity and evolutionary history of amphibians. It reflects a lifetime of specimen-based research on and thinking about the subject by the foremost student of early evolution of land vertebrates."
—Hans-Dieter Sues, National Museum of Natural History, Smithsonian Institution

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.php>

Reprints

Reprints of notes or articles published in ***HR*** may be ordered using the forms provided to authors with page proofs. Proofs are not sent to authors of Geographic Distribution or Natural History notes. Reprints may be ordered up to six months post-publication using the order form available at: <http://www.ssarherps.org/pages/HRinfo.php>

Advertising

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR web page (http://www.ssarherps.org/pages/HRinfo.php).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Central Michigan University, Department of Biology, 217 Brooks Hall, Mt. Pleasant, MI 48859, USA. Periodicals postage paid at Mt. Pleasant, MI 48859 and at additional mailing offices. All rights reserved. No part of this periodical may be reproduced without written permission of the Editor, except that authors and their agents are permitted to reproduce and distribute their own articles and notes. **POSTMASTER:** Send address changes to *Herpetological Review*, Allen Press, Inc., P.O. Box 1897, Lawrence, KS 66044, USA. Regarding missing or damaged issues, please notify *Herpetological Review*, Allen Press, Inc., P.O. Box 1897, Lawrence, KS 66044, USA (tel. 785/843-1234 or e-mail: herps@allenpress.com).

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <www.ssarbooks.com>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 840		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

ANNUAL DUES AND SUBSCRIPTIONS: Annual membership dues for the year 2009 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$70 (Student $35)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$95 (Student $50)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION (BASIC)** $140—includes *JH* and *HR*. **INSTITUTIONAL SUBSCRIPTION (COMPREHENSIVE)** $170—includes *JH*, *HR*, and *Catalogue*. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ssarherps.org/pages/membership.html.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its newsjournal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

To join SSAR or to renew your membership, please visit the secure online Allen Press website:

http://timssnet.allenpress.com/ECOMSSAR/timssnet/common/tnt_frontpage.cfm

Future Annual Meetings

2009 — Portland, Oregon, 22–27 July (with ASIH, HL)
2010 — Providence, Rhode Island, 7–12 July (with ASIH, HL)

About Our Cover: *Ranitomeya fantastica*

With brilliant colors and accompanying toxicity, fascinating parental behaviors, and convenient diurnal activity, dart-poison frogs in the family Dendrobatidae (*sensu lato*) have long attracted the attention of researchers. Arguably the most influential body of work resulted from the productive partnership of Charles Myers and John Daly (see p. 53 of this issue for a herpetological biography of Daly). For almost forty years, their collaboration yielded numerous new species, addressed taxonomic issues, and advanced the new field of anuran biochemical research. The work of Daly and his colleagues resulted in the discovery of over 800 chemical compounds isolated from dendrobatids, many novel and important in understanding broader physiological mechanisms beyond the herpetological realm.

More recent research has seen advances in our understanding of pattern polymorphisms, parental care, biogeography, and evolutionary theory. In 2006, Taran Grant and colleagues published a major systematic treatise (Grant et al. 2006. Bulletin of the American Museum of Natural History 299:1–262). New species continue to be described each year, with the total in late 2008 standing at over 260 (for the families Aromobatidae and Dendrobatidae combined; Frost 2008. Amphibian Species of the World: an Online Reference. Version 5.2 [15 July 2008]. Electronic database accessible at http://research.amnh.org/herpetology/amphibia/index.php. American Museum of Natural History, New York). An excellent source for additional information can be found at: www.dendrobates.org.

This issue's cover features *Ranitomeya fantastica*. Even for a veteran dendrobatid hunter, *R. fantastica* can be an extremely difficult frog to catch. They are very quick and have an amazing ability to completely disappear within leaf litter. This species is found in the Departments of San Martin and Loreto in central Peru and frequently is sympatric with *R. ventrimaculata* and *R. imitator*. *R. imitator* and *R. fantastica* are wildly polymorphic; our cover frog is representative of a population found adjacent to the city of Tarapoto, Peru. Recently, Brown et al. (2008. Zootaxa 1823:1–24) showed that *R. fantastica* consists of a complex of three species, two of which they described as new: *R. benedicta* and *R. summersi*. Our cover frog was photographed by **Tim Paine** in October 2006 using a Nikon D2x and a Nikkor 105mm macro lens (ISO 100, f/20). Lighting was accomplished using an SB800 flash (1/60 s) off-camera and Nikon's wireless R1C1 macro lighting set. Paine is a police officer with the San Francisco Police Department, and oftens travel to Latin America to photograph herpetofauna.

NEWSNOTES

Kansas Herpetological Society Annual Meeting

The Kansas Herpetological Society held its 35th Annual Meeting at Friends University in Wichita, Kansas, on November 8–9, 2008. Over 100 participants attended scientific paper sessions presented by scientists and students from across the nation. Featured speaker was Ronald Bonett (University of Tulsa).

Ashley Inslee, student at Fort Hayes State University, received the 2008 Howard K. Gloyd/Edward H. Taylor Scholarship, honoring the memory of two great biologists with strong ties to Kansas. The 2008 Alan H. Kamb Grant for Research on Kansas Snakes was made to Page Klug, Kansas State University, Manhattan. Dustin J. Wilgers, University of Nebraska, Lincoln, was chosen as the eleventh recipient of "The Suzanne L. & Joseph T. Collins Award for Excellence in Kansas Herpetology." Steve D. Grant, West Texas A&M University, was presented with the George Toland Award for the best student paper given at the meeting. In 2009, the Society will meet at Overland Park, Kansas.

MEETINGS

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (rwh13@csufresno.edu) well in advance of the event.

17–19 April 2009—Texas Herpetological Society Spring Field Meet, Rolling Plains Quail Research Ranch, near Roby, Texas, USA. Information: http://www.kingsnake.com/ths/2009_Spring%20Meet.htm.

19–23 April 2009—16th International Conference on Aquatic Invasive Species, Fairmont Queen Elizabeth Hotel, Montreal, Canada. A forum on Bullfrog Eradication and Control will be part of the program. Registration: http://www.icais.org/; information: www.bullfrogcontrol.com.

23–25 April 2009—56th Annual Meeting of the Southwestern Association of Naturalists, Monterrey, Mexico. Information: www.biosurvey.ou.edu/swan/annualm09.html.

6–7 June 2009—Southwestern PARC (Partners in Amphibian and Reptile Conservation) meeting and Herpetofauna Conservation Training (4–5 June), St. George, Utah, USA. Information: http://chelydra.unm.edu/swparc/.

17–20 June 2009—33rd International Herpetological Symposium, Monterrey, Mexico. Information: www.kingsnake.com/ihs.

18–20 July 2009—5th Meeting of the Snake Ecology Group, Donnelly, Idaho, USA. Registration and information: http://www.projectorianne.org/SEG_5.html.

22–27 July 2009—52nd Annual Meeting, Society for the Study of Amphibians and Reptiles; 89th Annual Meeting, Amercian Society

of Ichthyologists and Herpetologists; 67th Annual Meeting, The Herpetologists' League. Portland, Oregon, USA. Information: http://www.dce.ksu.edu/jointmeeting/.

16–17 October 2009—Texas Herpetological Society Fall Symposium, Texas A&M University, College Station, Texas, USA. Information: www.kingsnake.com/ths.

CURRENT RESEARCH

The purpose of Current Research is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, Joshua Hale or Ben Lowe; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can be found at: http://www.herplit.com/contents.

Looking for Commonalities in Amphibian Declines

Amphibian species across the globe are suffering from population declines and extinctions, many of which are due to the *Batrachochytrium dendrobatidis* (Bd) pandemic. Focusing on anurans, the authors used existing phylogenetic data and data on amphibian declines to look for factors that make some taxa particularly susceptible to rapid population declines. They compiled a dataset consisting of ecological, life history, and environmental data for 553 species (spanning 32 of 33 families and six continents). Additionally, the taxa were coded for IUCN status (e.g., threatened, endangered), if they have experienced rapid declines (RD) and the suspected cause of the declines (based on information from the Global Amphibian Assessment), and if Bd infection has been found (Bd+ and Bd-, respectively). The cause of decline was divided into three categories: habitat loss, over-exploitation, and "enigmatic" (which includes Bd, as well as UV exposure, climate change, etc.). Tests were conducted to determine if RD species were different from other threatened species, if enigmatic RD species were different from species experiencing RD caused by other factors, if Bd+ species experiencing RD differ from Bd+ species not experiencing RD, and if Bd+ species suffering from RD differ from Bd- species experiencing RD. For these tests, the confounding effects of phylogeny were accounted for by using a Generalized Estimating Equation. An aquatic life-stage was found to be strongly correlated with RD, relative to other threatened species. Relative to threatened species, species suffering enigmatic RD are significantly associated with both habitats experiencing low annual temperature variation and an aquatic life-stage. Furthermore, for Bd+ species, those experiencing RD exhibit a strong association with small distributions and high elevation. Finally, no associations were found for Bd+ species experiencing RD relative to Bd- species experiencing RD. This study shows that the connections between Bd, RD, and threatened status are complicated, with different factors leading to different results in anuran species.

Quantifying the Nutrient Contributions of Salamanders to Terrestrial Ecosystems

As organisms that develop as larvae in aquatic ecosystems, then emerge and move as adults to terrestrial ecosystems, many amphibian species potentially contribute greatly to the transfer of nutrients between these two environments. While this has been examined extensively in other systems, few studies have explicitly addressed the roll of amphibians in these types of biomass transfers. The authors sought to quantify this transfer in three species of *Ambystoma* (*A. tigrinum*, *A. opacum*, and *A. maculatum*) occurring sympatrically in four ponds (two temporary and two permanent) in Illinois. Using *A. opacum*, food-specific assimilation efficiencies were determined for three prey types: zooplankton (cladocerans and copepods), larval midges (*Chironomus*), and hatchling *A. maculatum*. Larval diets of the three species were determined through gut content analysis of ethanol-preserved specimens; prey numbers and sizes were also quantified. Using these data and species-specific population density data, the volume of food consumed by the larval salamanders (prey production), the amount assimilated, and amount of biomass transferred by each species to the terrestrial environment (all in g AFDM [ash-free dry mass] × m^{-2} [pond area] × $year^{-1}$) were calculated. In different pond types, the various prey species were found to contribute differently to the biomass transported to terrestrial ecosystems via metamorphosed salamanders. Different prey species were also found to contribute differently to the biomass of the various salamander species. In the three ponds in which salamander cohorts survived to metamorphosis, between 0.3 and 0.85 g AFDM m^{-2} $year^{-1}$ of biomass was delivered to terrestrial ecosystems by emerging salamanders, representing between 3.4% and 8.4% of prey production. This "emergence production" is considerably higher than has been found in most studies of similar systems, indicating that amphibians with both aquatic and terrestrial life-stages are very important contributors to the transfer of aquatic biomass to terrestrial ecosystems.

Regester, K. J., M. R. Whiles, and K. R. Lips. 2008. Variation in the trophic basis of production and energy flow associated with emergence of larval salamander assemblages from forest ponds. Freshwater Biology 53:1754–1767.

Comparative Biogeography Spanning the Strait of Gibraltar

The field of comparative phylogeography aims to understand the

effects of geography on biodiversity. One particularly interesting geographic feature, the Strait of Gibraltar, which separates the Iberian Peninsula from North Africa at the western terminus of the Mediterranean Sea, has long been of interest to evolutionary biologists. It currently is an effective barrier to dispersal to most terrestrial animals but was connected roughly 5.5 million years ago. Since that vicariant event, quantifiable morphological and/or molecular differentiation in taxon pairs occurring on either side of this feature may have accrued due to different selective pressures, founder's effects, or continued gene flow. To investigate this, the authors collected morphological and molecular data on eight taxon pairs divided by the Strait of Gibraltar spanning anurans, testudines, and squamates. The molecular data (mitochondrial DNA [mtDNA] and allozyme) is presumed to not be under selection and therefore give estimates of gene flow and degree of isolation between northern and southern populations. The morphological data is presumed to be under selection and therefore reflects the degree of differentiation due to selection attributable to the different environmental conditions existing in the two regions. Results suggest that the vicariant event led to different outcomes in the various taxon pairs. Three pairs (a hylid, a testudine, and a snake) exhibit low levels of genetic differentiation, suggesting continued gene flow between the two regions or recent colonization; however, discriminant analysis of the morphological variation revealed that the intercontinental morphological variation in the testudine was low while it was high in the anuran and the squamate. Two lacertid taxon pairs exhibited moderate to high morphological and mtDNA differentiation but low allozyme differentiation; this was attributed to limited gene flow during the formation of the isthmus via islands. Finally, the ranid, alytid, and, amphisbaenid taxon pairs exhibited moderate to high levels of morphological differentiation coupled with high levels of molecular differentiation, indicating the pairs diverged at, if not before, the formation of the isthmus and at least moderately different selective pressures are acting in the two regions.

Potential Effects of Climate Change on an Arid Lands Lizard

With the threat of climate change on the horizon, understanding its effect on wild populations is imperative. While initially it may seem that the increased global temperatures and longer growing seasons predicted by most climate models might be beneficial, studies have shown that climate change frequently triggers unforeseen detrimental effects. The author investigated the effects of extended growing season and milder winter temperatures in a northern population of side-blotched lizards (*Uta stansburiana*), a taxon that could potentially benefit from such changes. Eggs from wild caught females were hatched in captivity and hatchlings were measured, uniquely toe clipped, and either returned to the source population or released into one of twelve 100 m^2 enclosures located 38 km north of the source population. The enclosures were designed to encompass suitable habitat, complete with overwintering sites and potential mates and predators. The enclosures were populated on four dates, with the later dates allowing the lizards less time to accumulate fat reserves, simulating a shorter growing season. Lizards were recaptured at the end of the growing season and again the following spring (source population only) to ascertain survivorship and to make measurements. Additional lizards were collected from the source population at the end of the growing season and maintained in the laboratory at either 2.0° C or 7.7° C to ascertain winter survivorship. Lizards provided with longer growing periods were larger than lizards experiencing truncated growing seasons, lizards maintained at higher temperatures during winter experienced increased rates of mortality, and winter survivorship was found to be correlated with body size. These results reveal that while the lizards exhibit increased fitness with an increased growing season, this is offset by the lower survivorship of milder winters, attributable to an increased metabolism during hibernation.

Zani, P. A. 2008. Climate change trade-offs in the side-blotched lizard (*Uta stansburiana*): effects of growing-season length and mild temperatures on winter survival. Physiological and Biochemical Zoology 81:797–809.

Chytrid Epidemic in Wild Population Traced to Captive Bred Frogs

For many anuran species, captive breeding programs represent the only remaining option for reestablishing wild populations. However, *Batrachochytrium dendrobatidis* (Bd) has surfaced in a number of captive populations, leading to the possibility of Bd being introduced into wild populations by captive bred frogs. The authors document an unintentional Bd introduction in a population of *Alytes muletensis*, a critically endangered alytid endemic to the Mediterranean island of Malorca. Known wild populations were assayed for Bd, as were frogs that had died in the captive breeding program over the last two decades. Data on captive die-offs and introduction attempts were also gathered. Four of 21 populations tested positive for Bd, as did several captive frogs that had died between 1991 and 1995. Multilocus genetic analyses revealed the Bd in both the captive specimens and the wild populations belonged to the same strain, one unrelated to Bd strains known from mainland Europe. Furthermore, records revealed that in 1991 a *Xenopus* was brought into the breeding center; it was also found to have been infected with the same strain of Bd and it was only shortly thereafter that a large die-off of captive *Alytes* occurred. This unfortunate inadvertent introduction of Bd into a wild population underscores the importance of adhering to the IUCN guidelines for captive breeding.

Tracking the Evolution of Limb Reduction in Squamates

The growing number of well-supported phylogenies calibrated with a molecular clock has allowed researchers to answer questions regarding not only how many times a particular trait has originated within a clade, but also the timing of the change and how many different pathways have led to the derived state. Taking advantage of the recent availability of a robust, fossil-calibrated phylogeny for squamate reptiles, the authors investigated the evolution of a snake-like body form, which occurred no fewer than 26 times across the phylogeny. Data on eight morphological characters were collected for the 258 species included in the phylogeny on which regression analyses of independent contrasts were conducted to determine which traits were associated with limb reduction and to look for common patterns. Additionally, the terminal taxa in the phylogeny were coded for their forelimb and hind limb digit numbers and ancestral states were reconstructed across the phylogeny using a novel likelihood-based framework. Overall, forelimb and hind limb digit number were strongly correlated and reduction in limb lengths and digit numbers were strongly correlated with an increase in snout-vent length (SVL) and tail length (TL). Within some clades (Gymnophthalmidae and Scincidae), the correlation with TL dropped off; this was attributed to the discrepancy between the two different reduced-limb ecomorphs (long-tailed surface-dweller and the short-tailed burrower). Thresholds were found for limb lengths, SVL, and TL which when crossed a reduction in digit number invariably occurred. The median length of time between an ancestor with five digit limbs and a descendant missing at least one pair of limbs was found to be ~50 million years (My) and as short as ~16 My; lineages with extant members exhibiting morphologies intermediate between these two extremes have persisted for as long as ~63 My. Finally, instances of digit loss drastically outnumbered instances of digit gain and digit gain was found to occur more frequently in the forelimb than the hind limb.

M. C. Brandley, J. P. Huelsenbeck, and J. J. Wiens. 2008. Rates and patterns in the evolution of snake-like body form in squamate reptiles: evidence for repeated re-evolution of lost digits and long-term persistence of intermediate body forms. Evolution 62:2042–2064.

Thamnophis Pupil Diameter Changes with Water Submersion

The eye's pupil allows for adjustment to light conditions by widening and shrinking under low and high light conditions, respectively. Previous studies have shown that despite a reduction in available light, *Thamnophis* (North American garter snakes) submerged underwater experience reductions in pupil diameter. Potential benefits conveyed by a reduced aperture size underwater include an increased depth of field and an adjustment to the altered refractive index encountered in the different medium. Therefore, pupil diameter controlled by aqueous submersion (as opposed to light level) may allow aquatic snakes to better take advantage of underwater resources and variation in influence in light versus submersion control may allow for niche partitioning among sympatric species. To investigate this, the author examined pupil size response to light and submersion in three species of *Thamnophis* that occur sympatrically in southern California and exhibit different ecologies: *T. sitralis* (terrestrial), *T. hammondii* (aquatic), and *T. atratus* (intermediate). Light was found to have no impact on pupil aperture size. Additionally, while all species exhibited a reduced pupil size when submerged, *T. sirtalis* showed the largest magnitude of change (which was contrary to the prediction that the more aquatic species should show the greatest response to submersion). An explanation for this phenomenon lies in the absolute pupil size (which is smallest in *T. hammondii*); perhaps the aquatic specialists have abandoned pupil size flexibility and adequate but suboptimal vision both terrestrially and underwater (as seen in *T. sirtalis*) for an eye optimized for underwater vision at the expense terrestrial vision. This finding supports the hypothesis of niche partitioning.

Fontenot, C. L., Jr. 2008. Variation in pupil diameter in North American gartersnakes (*Thamnophis*) is regulated by immersion in water, not by light intensity. Vision Research 48:1663–1669.

Sea Turtle Evolutionary Relationships Obscure Origin of Spongivory

Studies examining the evolutionary relationships among extant sea turtles have offered conflicting results. The placement of the Australasian flatback turtle (*Natator*) has been particularly problematic; previous analyses have placed it as the sister taxon to a clade containing hawksbill (*Eretmochelys*), loggerhead (*Caretta*) and ridley (*Lepidochelys*) turtles. This relationship would have the unique spongivorous diet of *Eretmochelys* arising from an ancestral carnivorous condition. To address this question, the authors generated sequence data for two mitochondrial and five nuclear loci for all the extant sea turtles, including Pacific and Atlantic green turtles (*Chelonia*). Their analyses found *Natator* forming a clade with *Chelonia*, which in turn was sister to a clade containing all remaining sea turtles with the exception of leatherbacks (*Dermochelys*). This obscures the origin of spongivory, making it equally likely that it, the herbivorous diet of *Chelonia*, and the jellyfish diet of *Dermochelys* are derived from either a carnivorous or an omnivorous ancestral diet.

Recent Fossil Discovery Sheds Light on Amphibian Relationships

With a growing fossil record, it is clear that Amphibia is comprised of two clades, Temnospondyli and Lepospondyli. However, deciphering the origins of, and relationships among, the three extant amphibian lineages (Lissamphibia) has been problematic. Current hypotheses involve extant lineages forming a clade within Temnospondyli, forming a clade within Lepospondyli, or arising independently within Temnospondyli (Anura + Caudata) and Lepospondyli (Apoda). The authors describe a recent fossil from the early Permian and using morphological data, construct a phylogeny incorporating other known fossil amphibians. Their analysis reveals the new fossil is sister to the node-based clade defined by Anura and Caudata. Furthermore, Anura and Caudata are shown to be derived from within Temnospondyli while Apoda is derived from within Lepospondyli, rendering Lissamphibia paraphyletic. This phylogenetic reconstruction places the divergence between Temnospondyli and Lepospondyli within the Carboniferous, which is much more in line with molecular estimates than the monophyletic Lissamphibia hypotheses.

Fossil Reveals Morphological Evolution and Ecology of Early Turtles

Previously, early testudinate material indicated a terrestrial origin for modern turtles (= Testudines). The recent discovery from China of the earliest testudinate calls this hypothesis into question. *Odontochelys semitestacea*, from the early Carnian (mid Triassic; ~220 million years ago), appears to have inhabited the terrestrial-marine interface and superficially resembles extant aquatic turtles. In collaboration with other unique osteological features, the presence of teeth on most bones defining the oral cavity firmly places this taxon as the most basal testudinate (*Proganochelys*, the next most basal testudinate, possess teeth on a subset of those bones; later testudinates are toothless). *Odontochelys* exhibits a fully developed plastron but a rudimentary carapace; this sequence of shell evolution mirrors shell development seen in embryonic Testudines. Further examination of the carapace reveals the presence of axial skeleton elements with no osteoderm contribution. Finally, the addition of *Odontochelys* into a phylogenetic analysis of reptiles finds increased support for the placement of Testudinata within Diapsida.

OBITUARIES

Herpetological Review, 2009, 40(1), 5–6.
© 2009 by Society for the Study of Amphibians and Reptiles

Harlan D. Walley
November 7, 1932 – June 20, 2008

RICHARD B. KING
Department of Biological Sciences, Northern Illinois University
DeKalb, Illinois 60115, USA
e-mail: rbking@niu.edu

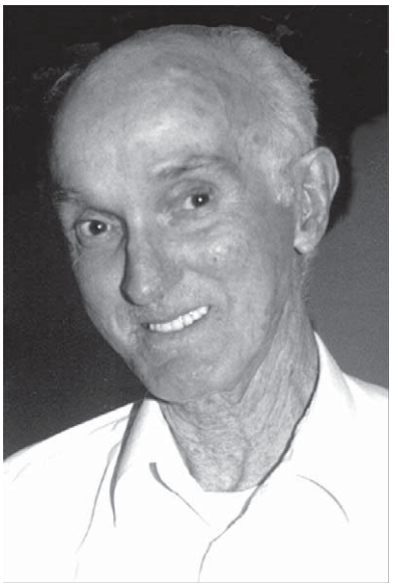

Fig. 1. Harlan D. Walley, ca. 2000.

Harlan Walley (Fig. 1) exhibited energy for life and love of natural history that began during his childhood in rural Sandwich, Illinois and continued throughout adulthood. He was a fixture in the Northern Illinois University Department of Biological Sciences, supervising the department's animal care facility from 1968 until his retirement in 1998 and curating its natural history museum until his death. Harlan's academic interests centered on herpetology, mammalogy, and Illinois natural history and he was a valuable, respected, and generous source of information to faculty, students, the community, and the state.

Harlan's formal training in biology was cut short by the Korean War, during which he served as a Navy medic (1951–1959), and by health problems associated with psoriasis which began during his years in Korea. Harlan suffered with this disease and a range of ineffective and sometimes harmful treatments for more than a decade before he found hydrocortisone ointments that allowed him to manage his symptoms. Time-consuming treatments, often at facilities far from home, interrupted his course work so frequently that he abandoned formal education beyond undergraduate classes at Waubonsee Community College and Northern Illinois University.

A true curator, Harlan became obsessed with natural history books and papers at an early age and went on to build a personal

collection of more than 60,000 reprints and 3,000 bound volumes. He developed his museum skills through time spent as a technician in the Departments of Entomology and Herpetology at the Smithsonian Institution and through an informal association with the Illinois Natural History Survey. At the INHS, Harlan established a lifelong relationship with two eminent figures of North American herpetology, Philip W. Smith, who in 1961 authored *The Amphibians and Reptiles of Illinois*, and Hobart M. Smith, who has continued to contribute to the scientific literature into his 90s. It was with Phil Smith that in 1951 Harlan published his first scientific paper—a note documenting the occurrence of the Marbled Salamander, *Ambystoma opacum*, in Michigan (Copeia 1951:309). Harlan was 18 at the time! Harlan went on to publish over 100 professional papers, many focused on amphibian, reptile, and mammal natural history and distribution. More than 30 of these appeared in *Herpetological Review* alone. He also put his reprint collection to good use, regularly contributing entries to the *Catalogue of American Amphibians and Reptiles*. The literature cited sections of his entries are encyclopedic—a soon to be published entry on the Northern Watersnake includes over 1,000 references! Harlan was an avid reader and supported this habit and his penchant for book collecting by authoring more than 100 book reviews, many of which can be found in the *Bulletin of the Maryland Herpetological Society*, *Bulletin of the Chicago Herpetological Society*, and *Wilson Bulletin.* Though focused on amphibians and reptiles, included among Harlan's publications are papers on fish, birds, mammals, and even freshwater jellyfish. For complete publication list, email rbking@niu.edu.

Harlan contributed to natural history education and conservation in many ways. He was an officer in local and state chapters of the Audubon Society, served a term as index editor for the American Society of Ichthyologists and Herpetologists, was a member of the Illinois Endangered Species Protection Advisory Board, and served on the Indiana Bat Recovery Plan panel. Perhaps one of Harlan's greatest, if unrecognized, contributions was the informal mentorship he provided to NIU biology graduate students. Harlan was a resource, lunch companion, and field-trip guide to students with interests in any aspect of biology. He was generous with his reprint collection and often helped start students' publishing careers by urging submission of a life history or distributional observation or including them as coauthors on papers he initiated. He enriched all our lives in unfathomable ways and will be missed!

Updating the Bookshelves Part III: Important Herpetological Books Appearing During the Last Two Decades

GENERAL— REGIONAL WORKS— SNAKES— LIZARDS

FOR HIM THAT STEALETH, OR BORROWETH AND RETURNETH NOT, THIS BOOK FROM ITS OWNER, LET IT CHANGE INTO A SERPENT IN HIS HAND AND REND HIM. LET HIM BE STRUCK WITH PALSY, AND ALL HIS MEMBERS BLASTED. LET HIM LANGUISH IN PAIN CRYING ALOUD FOR MERCY, AND LET THERE BE NO SURCEASE TO THIS AGONY TILL HE SING IN DISSOLUTION. LET BOOKWORMS GNAW HIS ENTRAILS . . . AND WHEN AT LAST HE GOETH TO HIS FINAL PUNISHMENT, LET THE FLAMES OF HELL CONSUME HIM FOREVER.

—*A Gentle Madness*, Nicholas A. Basbanes, 1995.

I have selected books, mostly from my library, which have been helpful as sources of information and, in my view, deserve a place in every zoo herpetologist's reference collection. Each entry includes title, author(s), call number or ISBN, place of publisher, name of publisher, and date of publication. Titles are listed alphabetically by author. Due to space limitations, I have decided not to include books covering a single genus, e.g., *Phelsuma*, *Rhacodactylus*, *Eublepharis*, which are geared toward the herpetoculturist. Books mentioned in Parts I and II are not listed here. Part IV will appear in the next issue.

MULTI-VOLUME CONTINUING SERIES

Grzimek's Animal Life Encyclopedia / / Bernhard Grzimek.
QL7.G7813 2003X
Imprint: Detroit MI: Gale, 2003.

Amphibian Biology / / edited by Harold Heatwole.
q QL667 .A52 1994
Imprint: Chipping Norton, NSW, Australia: Surrey Beatty & Sons, 1994-

In addition to the journal *Salamandra*, the book series Mertensiella is published by Deutsche Gesellschaft für Herpetologie und Terrarienkunde (German Society for Herpetology and Terrariums). Recent topics include biology of Nile Monitor, three books on varanid lizards, ecology of European Pond Turtle, mating biology of squamates, field techniques, history of herpetology and herpetoculture in German-speaking areas, and conservation and natural history of the Green Toad, European Viper, and Emerald Lizard.

In addition to its journal and news-journal, the Society for the Study of Amphibians and Reptiles (SSAR) has five continuing series: *Catalogue of American Amphibians and Reptiles*, *Herpetological Conservation*, *Contributions to Herpetology*, *Facsimile Reprints in Herpetology*, and *Herpetological Circulars*. A complete list of titles may be found at the back of any book published by SSAR.

The Herpetologists' League publishes *Herpetological Monographs* in addition to the journal *Herpetologica*.

The Center for North American Herpetology Facsimile Reprints Series was established in December 2005 and ten titles have been published:

The Herpetology of Hispaniola / / Doris Cochran (1941; ISBN 1-885209-00-2)

A Revision of the Kingsnakes: Genus *Lampropeltis* / / Frank N. Blanchard (1921; ISBN 1-885209-45-2).

The Poisonous Snakes of North America / / Leonhard Stejneger (1895; ISBN 1-885209-47-9).

Variations and Relationships in the Snakes of the Genus *Pituophis* / / Olive Griffith Stull (1940; ISBN 1-885209-46-0).

The Hellbenders / / Max Allen Nickerson and Charles Edwin Mays (1972; ISBN 1-885209-43-6).

Fossil Turtles of North America / / O. P. Hay (1908; ISBN 1-885209-44-4).

Rhinoceros Viper (*Vipera nasicornis*, now *Bitis nasicornis*) in *Snakes: Curiosities and Wonders of Serpent Life*, by Catherine Cooper Hopley in 1882. This book was one of the most accurate books on snakes published at the time. In the last chapter entitled "Notes from the Zoological Gardens," she discussed some of the snakes at the London Zoo, including the King Cobra, Rhinoceros Viper, Cottonmouth, and Neotropical Rattlesnake.

Imprint: London, Griffith & Farran.

One of the most perfectly balanced and lovely snake drawings in the history of herpetological art was created by the artist R. Mintern and lithographer J. Green—Neotropical Rat Snake (*Spilotes salvini*, now *S. pullatus*) from Albert C. L.G. Günther's *Biologia Centrali-Americana. [vol. 7], Reptilia and Batrachia*, 1885–1902. The major reason why this image is so striking is this arboreal snake was shown entwined in branches in a naturalistic pose.

Imprint: London, Pub. for the editors by R. H. Porter.

The Herpetology of Michigan / / Alexander G. Ruthven, et al. (1928; ISBN 1-885209-49-5).

The Whip Snakes and Racers Genera *Masticophis* and *Coluber* / / Arthur Irving Ortenburger (1928; ISBN 1-885209-50-9).

Turtles of the Northeastern United States / / Harold L. Babcock (1919; ISBN 1-885209-51-7).

The Reptiles and Batrachians of North America / / Samuel Garman (1883; ISBN 1-885209-48-7).

SNAKES

Snakes of the World / / Manuel Aresté and Rafael Cebrian.

Three views of the Pine or Bull Snake (*Pituophis melanoleucus* sensu lato) and varieties from the 19th century—*North American Herpetology; or, A Description of the Reptiles Inhabiting the United States*, by John Edwards Holbrook in 1842; *United States Exploring Expedition: during the years 1838, 1839, 1840, 1841, 1842, under the command of Charles Wilkes, U.S.N.; [v. 20]*, by Charles Girard, 1858; *Iconographie générale des ophidiens / par M. le professor Jan . . .*[*en collaboration avec Mr. F. Sordelli*.]. . . , 1860–1881.

Herpetology from A to Z

In 1964, James A. Peters wrote *Dictionary of Herpetology: A Brief and Meaningful Definition of Words and Terms Used in Herpetology*. Since my memory is not stellar, I used this book constantly until my copy was worn and tattered. Forty-four years later, my recall has certainly not improved but at least I can turn to a new source to refresh and refine my recollection of biological and herpetological terminology—*Dictionary of Herpetology* by Harvey B. Lillywhite (2008, Krieger Publ. Co., Malabar FL; Hardcover, 8.5 x 11, 384 pages; ISBN 1-57524-023-8). Lillywhite's book will be useful for decades: 11,358 readable definitions related to anatomy, physiology, systematics, evolution, and other disciplines in an alphabetical format.

Lillywhite's book contains over three times the number of entries found in the dictionary by Peters. One important element is the inclusion of recent terminology which updates the tools, methods and concepts from a variety of biological disciplines relevant to the study of amphibians and reptiles. Of particular value is the provision of a literature citation(s) accompanying many terms so the reader can go to the original source. For instance, the definition of the word species almost fills an entire page and identifies dozens of titles. In Peters, that word is not listed.

There are three tables: geologic time; International System of units, conversions, constant, and definitions; and metric prefixes and multipliers. This dictionary includes 41 figures to complement the text. Another feature is inclusion of the new taxonomic arrangements proposed in 2006 by Darrel Frost and 18 coauthors—The Amphibian Tree of Life (Bull. Amer. Mus. Nat. Hist. No. 297:1–370).

Some may complain that the list price of US $112.50 is pretty steep but that translates to around 1¢ a word in United States currency. That seems like a pretty good deal to me, especially since the value of the dollar is shrinking.

"Today, the only chance one has to see a Rim Rock Crowned Snake is on a public or private wildlife reserve. The days of finding this species in a suburban Miami backyard or under a piece of limestone at the side of a roadway spanning a rural zone between south Florida towns are gone. One day soon this will be the case for most of the species highlighted in these pages."

—Steven B. Reichling, 2008

Steven B. Reichling, Curator of Reptiles and Aquarium at the Memphis Zoo and adjunct professor of biology at the University of Mem-

phis in Tennessee, has written a book on the herpetofauna found in the southeastern United States. The book is well written, clearly organized, and filled with excellent photographs but reading through this book was a bittersweet experience. I have traveled periodically to some of these places since I was a child and have watched many of them disappear before my eyes. When I saw the type locality (depicted in plate 7.3 in the book) for the Rim Rock Crowned Snake (*Tantilla oolitica*) strewn with trash and surrounded by buildings and a chain link fence in Miami, it was a reminder of how ravaged the land has become in southern Florida. But enough of this maudlin recollection—most herpetologists can say the same when thinking about changes to their favorite haunts.

Reichling's book—*Reptiles & Amphibians of the Southern Pine Woods* (2008, University Press of Florida, Gainesville, softbound, ISBN 978-0-8130-3250-4)—covers the pine woods from Texas to North Carolina, south to the Gulf of Mexico and north to the Appalachians. Twenty-six species or subspecies are highlighted and each account includes Description, Distribution Notes, Habitat, Ecology and Natural History, Conservation, and a Summary. Twenty-six distribution maps are included. Species are grouped by habitat types: pine woods generalists, flatwoods specialists, savanna specialists, ridge specialists, rockland specialists, and others. In the epilogue, Reichling passionately describes the daunting conservation task ahead: "What happens—or fails to happen—during the next four crucial decades will determine whether the species accounts and habitat descriptions in the preceding pages are still relevant and accurate, or have become an historical record of times and places lost to future generations."

He is well-qualified for writing this book as he has extensive experience with some of the prominent denizens of these forests: the endangered pine snakes of the Gulf Coast. His studies include reproduction in captive Black Pinesnakes, *Pituophis melanoleucus lodingi*; as well as reproductive biology, taxonomic status and its relevance to the evolutionary species concept, and current status of the endangered Louisiana Pinesnake, *P. ruthveni*. He has published the AZA's North American Regional Studbook for both of these taxa. Reichling has published other herpetological papers: dystocia in snakes, habits of the Mangrove Snake in captivity, reproduction in captive Dumeril's Boas, conservation status of the Lesser Antillean Iguana, and phenotypic consequences of incubation environment on cobra eggs in the African elapid genus *Aspidelaps*. He is also author of a book on tarantulas of Belize.

Biology of the Reptilia

The first volume of the series entitled *Biology of the Reptilia* was published in 1969. The general editor for the entire project was Dr. Carl Gans, now an adjunct professor at the University of Texas at Austin. His plan was to produce a timely and comprehensive series of books dealing with all aspects of reptilian biology; he solicited specialists to prepare chapters reflecting their areas of expertise. Gans invited co-editors versed in morphology, embryology and physiology, or ecology and behavior.

Twenty-one volumes have been published which represent the most complete coverage of these topics ever assembled. These books represent the highest scholarship and are essential for advanced zoo herpetologists who wish to go beyond current husbandry literature in an effort to understand the principles and dynamics of the processes which reflect the complexities of captive reptiles.

The final two text volumes (20, 21), published as a set, are available from SSAR and contain the following chapters: "The Skull of Lizards and Tuatara" by Susan E. Evans; "The Snake Skull" by David Cundall and Frances Irish; "The Appendicular Locomotor Apparatus of *Sphenodon* and Normal-limbed Squamates" by Anthony P. Russell and Aaron M. Bauer; "The Skull of Serpentes" by Samuel B. McDowell; "An Atlas of Amphisbaenian Skull Anatomy" by Carl Gans and Ricardo Montero.

Madagascar is internationally recognized as being of high biodiversity conservation concern due to high levels of endemism, habitat destruction and predicted extinctions (Brooks et al. 2002; Myers 1988; Myers et al. 2000). The herpetofauna of Madagascar in particular is extremely species-rich and diverse with high levels of endemism (Glaw and Vences 2007).

Conservation strategies are in place to protect this unique biodiversity, including identification of priority areas in Madagascar for threatened or overall species diversity and their inclusion in protected nature reserves (Ganzhorn et al. 1997; ANGAP 2001). In theory these protected nature reserves are an effective means to protect tropical biodiversity (Bruner et al. 2001) and they can be successful at stopping land clearing, and to a lesser degree effective at mitigating logging, hunting, fire, and grazing (Bruner et al. 2001). However, in practice the identification and protection of priority areas globally is constrained by a lack of information regarding the distribution, abundance, and habitat requirements of threatened species and the size, condition, and threats to survival of forest remnants (Smith et al. 1997). This type of baseline information is needed to integrate information relevant to existing conservation and development programs and guide the course of future management strategies (Balmford and Gaston 1999; Kremen et al. 1994; Andreone et al. 2008; Kremen et al. 2008).

Furthermore, the regions in Madagascar where conservation management is most needed are also the regions where biological information is most limited (i.e., primary habitats located within non-protected areas [Andreone et al. 2003; D'Cruze et al. 2006; Kremen et al. 2008]). As a result, decisions affecting biodiversity often have to be taken without all the necessary information (data may be unavailable, incomplete, or unreliable [Funk and Richardson 2002]). This is partly because many surveys, in Madagascar and elsewhere, are conducted over a fairly short period of time, and often within sites that are already been designated as protected areas (e.g., Bildstein 1998; Gaston and Rodrigues 2003; Goodman 1999; Raxworthy and Nussbaum 1994). It is widely accepted that there are major financial, labor, and time-related constraints associated with conducting such work (Bildstein 1998).

Given the necessity for adequate baseline information to conserve this important region of biological endemism, we conducted a literature review of herpetological surveys published for Madagascar. We chose reptiles and amphibians as focal taxa because in Madagascar these vertebrate groups are highly endemic, species-rich, currently under threat, and often serve as excellent indicator species (Raxworthy 1988). We focused on papers published between 1994 and 2007 because prior to 1994 the knowledge of most Malagasy amphibians and reptiles was largely based on the studies of a few herpetologists who often provided comprehensive accounts and revisions (e.g., Blanc, Blommers-Schlosser, Brygoo and Domergue; Glaw and Vences 2007). Since 1994, a new research era has started in Madagascar, stimulated by the publication of a new field guide (Glaw and Vences 1994). Large-scale surveys and species inventories have subsequently been carried out by a new generation of more numerous researchers, operating in a much more collaborative manner, in many areas of Madagascar, including well-known sites and hitherto unexplored remote regions (Glaw and Vences 2007; Vences et al., *in press*).

We undertook this study to: 1) characterize the types of herpetological survey work conducted over the past two decades; 2) use this information to identify any biases in survey work conducted to date to guide future herpetological research initiatives; and 3) highlight any weaknesses so as to provide potential solutions to limiting factors which might be inhibiting such work.

Methods

Literature Review.—We conducted a literature review of peer-reviewed scientific journals to compile a comprehensive list of herpetological survey-based published manuscripts. This type of information can be embedded in manuscripts focused on ultimate function (i.e., "why" something happens [Timbergen 1963]) making the data difficult to identify. Therefore, we specifically searched for manuscripts that included a detailed species inventory or list. However, any attempt to document survey/inventory-based manuscripts will have a degree of subjectivity involved (McCallum and McCallum 2006), and this study is no different. Still we made every effort to accurately portray what is and what is not a survey-based manuscript and to take the most inclusionary and liberal approach possible to classify manuscripts.

Following the completion of this review we subjected tabulated data to simple regression analysis using Systat statistical software (version 10.0, Systat Software Inc., San Jose, California, USA). We analyzed publications to reveal the number of papers published per year over the selected study period. We chose to ignore the duration of each survey as we were unable to determine the number of staff actively participating during fieldwork and ensure an unbiased comparison. In addition, we assembled a data set that included the protective status and dominant vegetation types of each survey site (we designated four categories for the purpose of this study: rainforest, dry deciduous forest, savanna, and spiny forest). We also tabulated various aspects of the survey methodology, including focal taxa, season, and capture methods used. Finally, when possible we recorded the primary funding source as listed in the acknowledgments section of each manuscript.

Results

We found 37 herpetological survey-based published manuscripts (Table 1), based on surveys conducted in 31 different locations by 19 different primary authors. Five of these primary authors (26%) are Malagasy nationals. The remaining 14 (74%) are non-Malagasy nationals. Twelve (32%) of these 37 publications included Malagasy nationals as either a primary or co-author. Between 1994 and 2007 the number of survey-based manuscripts varied between 1 and 5 publications per year, with an average of 2.6. Linear trends analysis revealed that the number of survey-focused manuscripts published per year has remained relatively constant ($R^2 = 0.01$, $P = 0.738$) (Fig. 1).

Protected areas have been subject to more survey effort than unprotected areas (Table 1), as 22 surveys (59%) were conducted in areas currently awarded full protection (Strict Nature Reserve 3%, Special Reserve 8% and National Park 49%; Table 2). The remaining 15 sites (41%) are currently unprotected or have only been recently awarded Temporary Protected Status (Unprotected 38%, Temporary Protected Area 3%). However, it is important to note that despite this preference for protected areas only 17 of the 49 (35%) fully protected areas in Madagascar have been subject to published herpetological survey work.

The different vegetation types in Madagascar have also not been subject to equal survey effort (Table 1), as 26 (70%) of these 37 studies involved survey work in rainforest habitat, 13 (35%) involved survey work in dry deciduous habitat, 4 (11%) involved survey work in spiny forest habitat and one (3%) involved survey work in savanna habitat. With regards to focus taxa, we found that 32 publications (86%) focused on both reptiles and amphibians, three (8%) focused just on amphibians, and two (6%) focused solely on reptiles.

We also extracted information from our literature review regarding the seasonal aspect of each survey. We classified surveys as 1) dry season (May–October); 2) wet season (November–April); or 3) wet and dry (some field work conducted during both of the aforementioned periods). Seventeen (46%) of these 37 surveys involved field work conducted in the wet and dry season. Of the remaining surveys, 15 (41%) only involved field work conducted in the wet season, two (5%) only involved field work conducted in the dry season and three (8%) provided no information.

We also extracted information on the survey techniques used in each survey. Active searching was utilized in all of the surveys, while pitfall trapping was used in 29 (78%) to capture specimens. We were able to glean information regarding funding (from the acknowledgment sections) from 22 of the 37 manuscripts. All but three studies involved some form of research grant from a scientific or industrial benefactor, and five studies used volunteers in some capacity during field work.

Discussion

Herpetological survey work trends in Madagascar.—A prior analysis of a list of almost 1400 publications focused on Malagasy amphibians and reptiles revealed a clear trend of increasing research intensity from the year 1838 until the present day with maximum levels reached for the periods of 1990–1999 and 2000–2009 (Vences et al., *in press*). In contrast, we found that the number of published manuscripts focused on herpetological survey work appear to have remained relatively constant during the period 1994–2007. Initially, one might assume that a similar marked increase in this particular type of scientific research has not occurred as it is not required. For example, it may be that already there is sufficient information available in the existing literature (detailing the composition, geographical, ecological, and seasonal distribution of the herpetofauna in Madagascar) and that the majority of these surveys are monitoring efforts conducted to observe changes in population dynamics or community structure. However, unfortunately this is not the case and this is exemplified by the number of new species which continue to be described each year (Glaw and Vences 2007; Vences et al., *in press*) and by the fact that our study shows that the existing data currently available as a result of herpetological survey work is far from comprehensive. We estimate that it will take approximately another 20 years before even a preliminary herpetological species list is available for all of the current protected areas in Madagascar.

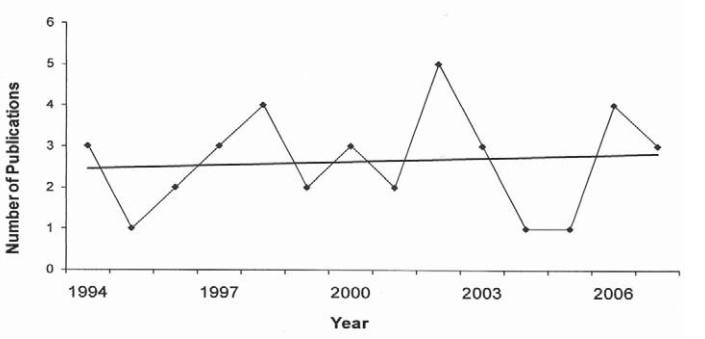

Fig. 1 Publication of herpetological survey-based manuscripts 1994–2007. Points are observed values and the line represents the trend.

It is important to note that this observed trend might not be a direct reflection of the amount of field work that has actually being conducted over this time period. It is more than likely that researchers have been gathering these sorts of data without publishing their findings in a peer-reviewed format (Vences et al., *in press*). Either way, despite their recognized value (Greene and Losos 1988; Greene 1994, 2005), we suspect that the number of peer-reviewed survey-based studies published over this period might have been restricted because of the strong natural history component which is present in this type of manuscript (studies have indicated that the publication frequency of natural history studies has gradually declined over recent decades [Bury 2006; McCallum and McCallum 2006]). Explanations for these kinds of restrictions are complex but might be related to the fact that conservation and science are driven by different agendas (a lot of conservation science published in respectable journals will be of little use to practical conservation, while much good conservation practice would never get into a scientific journal). Peer-reviewed journal editorial strategies are driven by scientific agendas which are often subject to fads and fashions (R. Griffiths, pers. comm.). Therefore, factors affecting the publication trends of survey-based manuscripts will include less grant funding, editorial decisions, additional competition from other journals, and the rise of molecular and genetic studies (McCallum and McCallum 2006).

Unequal sampling effort.—In their prior analysis of a list of almost 1400 publications Vences et al. (*in press*) found that research on Malagasy amphibians has been less intensive as compared to reptiles. In contrast, we found that the majority of survey-based

manuscripts published over the last 14 years (86%) provide information for both reptiles and amphibians. This is more than likely because traditional survey techniques used to target either reptiles or amphibians (e.g., visual encounter surveys [Campbell and Christman 1982] and pitfall trapping [Raxworthy and Nussbaum 1994]) typically result in the capture of species belonging to both of these vertebrate groups (Raxworthy 1988).

However, it appears that this survey work has not been so equally distributed throughout Madagascar with regards to the protective status of study areas. For example, we found that the majority of published survey work has been conducted in protected areas. This is understandable as only 35% of protected areas have been surveyed and this information is needed to manage them correctly. However, this means that the designation of future protected areas is greatly compromised. Furthermore, at least from a herpetological point of view, our study confirms prior claims that there have been lower conservation efforts in the dry deciduous forests, spiny forest and savanna areas of Madagascar when compared to those undertaken in Madagascar's evergreen rainforest (Ganzhorn et al. 2001). Explanations for this type of site bias are difficult to qualify;

TABLE 2. Details of the current ANGAP protected areas and related herpetological survey effort.

Province	Number of Surveys Conducted in non-ANGAP Protected Areas	Number of Surveys Conducted in ANGAP Protected Areas	Number of ANGAP Protected Areas	% ANGAP Protected Areas Surveyed
Toamasina	2	0	9	0
Mahajanga	0	4	12	17
Fianarantsoa	2	4	7	43
Antsiranana	5	5	10	50
Toliara	4	8	10	60
Antananarivo	2	1	1	100
Madagascar	15	22	49	35

however, this might be because these rainforest sites are more accessible, because more preliminary research has been conducted in this type of habitat or because the majority of protected areas are composed of rainforest habitat. Additionally this may be because of the perceived greater biological richness of this habitat type or because this type of habitat is not characterized by such pronounced seasonal variation (meaning that researchers do not have to worry about associated decreases in herpetological activity). Finally, it is also important to note that the relative area for each of the habitat types is different and might also be an influencing factor that is partly responsible for this observation.

Addressing the limitations of current survey work.—One important first step to address this situation would be to encourage and facilitate the further participation of Malagasy researchers. For a long time the participation of Malagasy researchers in the exploration work and publications of Madagascar's flora and fauna remained marginal, largely reflecting colonial history (Vences et al., *in press*). Although it has now been recognized Malagasy scientists can (and have in recent decades) strongly contribute to advancing the knowledge on Madagascar's biota (there is an increasing trend in the participation of Malagasy researchers in the process of publishing research results [Vences et al., *in press*]), we found that only 33% of the survey-based manuscripts published in the last 14 years included Malagasy researchers as either primary or co-author. In a similar study, researchers also found that more than 80% of all studies on Malagasy amphibians are published without the participation of Malagasy researchers (Vences et al., *in press*).

Another key step that could be made to address this situation would be to foster the participation of non-specialist, self-funded volunteer researchers (hereafter referred to as volunteers). Volunteers have been seen as a viable option by host countries with financial, labor, or training constraints (Mumby et al. 1995) which is apparent from their increasing contribution to conservation biology and wildlife management over the past 20 years (e.g., Bildstein 1998; Easa et al. 1997; Fore et al. 2001; Foster-Smith and Evans 2003; Gill 1994; Newman et al. 2003). However, our study indicates that over the last 14 years in Madagascar only four studies (Andreone et al. 2003; D'Cruze et al. 2005; D'Cruze et al. 2007; Raxworthy and Nussbaum 1994) utilized volunteers and only two of these (D'Cruze et al. 2005; D'Cruze et al. 2007) were solely reliant on them as a source of funding. We suggest that the under-utilization of volunteers in Madagascar is due to the fact that their use in scientific research is often criticized. A major problem is that data that they generate are considered unreliable both because many volunteers lack a high level of biological knowledge and training, and due to inconsistencies through the use of many different observers (Bildstein 1998; Darwall and Dulvy 1996). Another worry relating to the use of volunteers is that they may be seen as a solution to the issue of under-funding, leading to further reductions in research funds.

In our opinion both of these groups should be viewed as key collaborators that have the potential to help in addressing the financial, labor, and time-related constraints associated with conducting modern survey work. We highly recommend that researchers should seek to increase collaboration and initiate capacity-building exercises to ensure the systematic collection of reliable and comparable data. This should include the collation of digital photos, morphological data, molecular tissue samples, call recordings, specimens, and associated ecological data.

Making survey data accessible.—The accessibility of data generated by modern survey work is also of fundamental importance. For example, it is possible that survey-based studies resulting in peer-reviewed manuscripts might have limited utility for practical conservation because a) many conservation practitioners do not have access to peer-reviewed manuscripts, and b) unpublished (i.e., "grey literature") reports might be more accessible to those who need to utilize these data (e.g., park management authorities). However, at the same time, because grey literature reports have typically not been subject to peer review their scientific and technical accuracy can be brought into question, and they are not always accessible to other external stakeholders (e.g., international NGOs).

A general change in the way that survey data are distributed might be required to ensure that data are made available to relevant stakeholders. To achieve this, several researchers (Rhee 2004; Vences et al., *in press*) have proposed to make data available through appropriate cyber structure and an electronically connected network of knowledge. Specifically, they propose that data should be published electronically and made instantly available on a seamless connection of community databases, public repositories, and journals. As a result, the data collected during herpetological survey work would no longer remain isolated in specialized papers and grey reports. The Réseau de la Biodiversité de Madagascar (REBIOMA) project (which aims to make validated, up-to-date biodiversity data available for conservation planning in Madagascar and to provide conservation tools and map products to facilitate identification of conservation priorities)

could serve as the "embryo" for such an online resource. Progress towards this vision will require a high degree of collaborative effort. However, it appears that research on Malagasy amphibians is already a collaborative endeavor (exemplified by the increasing number of authors and nationalities involved in the publication of such papers [Vences et al., *in press*]) and therefore this is a feasible potential future strategy.

CONCLUSION

It appears that time, personnel, and financial resources have limited the amount of herpetologically-focused survey work conducted in Madagascar, which unlike other fields of herpetological biology, such as taxonomy, has remained relatively constant over the past two decades. The rapid and increasing rates of habitat loss make protective management and reserve selection in Madagascar an urgent task. Therefore, we recommend that more surveys should be conducted in Madagascar (both in protected and unprotected areas) and that researchers should look to work in habitat types that have been traditionally overlooked. Research programs should increase collaboration with Malagasy researchers and self-funded volunteers, as both groups provide the means by which comprehensive data sets can be collected and both can

effectively contribute to long-term surveys. We also support the increasingly collaborative nature of research on Malagasy herpetofauna by utilizing approaches that speed up data availability via appropriate cyber infrastructure.

Acknowledgments.—Thanks go to Richard Griffiths, Miguel Vences, Frank Glaw, Sunil Kumar, Bill Branch, Richard Jenkins, Simon Loader, Jeremy Sabel, and Chris Raxworthy for their comments and guidance on earlier drafts of the manuscript.

Eyes Bigger than Stomach: Prey Caching and Retrieval in the Saltwater Crocodile, *Crocodylus porosus*

J. SEAN DOODY
Institute for Applied Ecology, University of Canberra, ACT 2601, Australia

Present address:
Department of Botany and Zoology
Australian National University, ACT 2600, Australia
e-mail: sean.doody@anu.edu.au

Some animals store surplus food for later consumption (reviewed in Smith and Reichman, 1984; Vander Wall, 1990). For example, herbivores such as squirrels cache nuts for consumption during winter when food is less abundant (Smith and Follmer 1972). Long-term caching is possible for carnivores in cold climates, but predators can cache prey for several days in any climate. For example, leopards cache prey in trees to reduce competition from other scavengers (Kruuk 1972). Prey caching in carnivores is known for felids, hyenas, canids, bears, mustelids, shrews, birds of prey, and seals (Ingram 1942; Kim et al. 2005; Kruuk, 1972; McCord 1974; Michener 2000; Oksanen 1983; Phillips et al. 1990; Schaefer et al. 2007; Smith and Reichman 1984). The general explanation for this behavior is that a predator caches when its prey is too large to consume in one feeding bout (Smith and Reichman 1984), although surplus killing of smaller prey may also occur when predators are already satiated (Kruuk 1972; Oksanen et al. 1985).

Crocodilians are capable of killing prey much larger than their stomachs, and Webb and Manolis (1989) report that Saltwater Crocodiles (*Crocodylus porosus*) cache their recent kills underwater or in mangroves. *Crocodylus porosus* is a large crocodilian inhabiting rivers, estuaries, and swamps from northern Australia through to southeast Asia and eastern India (Webb and Manolis 1989). Like other crocodiles it is a generalist carnivore, feeding on a variety of invertebrates, fish, amphibians, reptiles, birds, and mammals (Taylor 1979; Webb and Manolis 1989; Webb et al. 1991). Larger individuals are known to capture medium to large terrestrial prey such as wallabies, cattle, and water buffalo (Doody et al. 2007; Pye 1976; Shield 1994; Webb and Manolis 1989).

Crocodylus porosus is relatively common in the Daly River, Northern Territory, Australia, where in recent years we have studied anti-predator behavior in Agile Wallabies, *Macropus agilis*, in response to the threat of crocodile predation (Doody et al. 2007; Steer 2007). During the dry seasons (May–October) of 2001–2007 my colleagues and I made a number of observations of prey caching by crocodiles in freshwater reaches between Oolloo Crossing (14.005ºS, 131.2402778°E) and Daly River Township (13.7747222°S, 130.7211111°E). We located crocodile kills via boat. Our evidence for kills was generally indirect or circumstantial (e.g., wallabies with missing heads or limbs, or with obvious crocodile bite marks). These kills were considered to be caches when there was evidence of manipulation by crocodiles (e.g., carcasses placed above water on snags, or on riverbanks with associated crocodile tracks). Cache retrieval was documented opportunistically using remote camera systems. I used Trailmaster® camera systems, which consist of an infrared emitter box, a receiver with LED, and a 35mm camera. The system was employed such that a crocodile retrieving a carcass would break the infrared beam, triggering the camera mounted above. Herein, I summarize the findings and discuss a previously unpublished behavior in crocodiles—above-water prey caching. I also report a possible case of surplus killing in *C. porosus* associated with prey caching.

Thirty-eight prey caches of *C. porosus* were discovered during 2001–2007, including mammals, reptiles, a fish, and a bird (Table 1). The most common prey item cached was the Agile Wallaby (*Macropus agilis*), for which 28 carcasses were found. Individuals were usually found floating, either at the river's edge or lodged on woody snags, but in eight instances wallabies were dragged onto the riverbank (Fig. 1). For example, in 2001 an adult female wallaby carcass was found 5 m up a steep sand bank and footprints and marks in the sand revealed that the carcass had been dragged there by a large (~3 m) crocodile. I employed a camera system just below the carcass in an attempt to photograph the crocodile returning, but the carcass was dragged further up the slope by unknown predators, possibly dingos. However, in the same year, a camera system did reveal a ~3 m crocodile returning for a wallaby cache (Fig. 1). The carcass was found the previous day at the river's edge with puncture wounds to the neck and head, and I employed a camera trap that afternoon. The crocodile retrieved the carcass at 0440 h the following morning (Fig. 1).

Two days later I discovered the carcass of a Northern Quoll (*Dasyurus hallicatus*) on a nearby vegetated riverbank, 2 m from the river. Crocodile tracks in the sand suggested that a ~3 m crocodile had cached the quoll. I employed a camera system that afternoon, and a crocodile retrieved the carcass at 0537 h the next morning (Fig. 2). Interestingly, the quoll was found < 100 m from where the abovementioned wallaby had been killed, cached, and retrieved, suggesting that the same crocodile was responsible for both kills. This could explain why such a small prey item was cached rather than immediately consumed.

Other mammals found cached were Water Buffalo (*Bubalus bubalis*), one of which was found floating but lodged against a snag, with obvious 'towing' teeth marks at the base of the tail, and a feral pig, in which a front quarter was lodged on a snag just above water. Reptile caches found were snakes and turtles (Table 1). A Pig-nosed Turtle (*Carettochelys insculpta*) cache with crocodile teeth marks was located on a snag just above the water. A Black-headed Python (*Aspidites melanocephalus*) was cached on a riverbank next to tracks of a ~2.5 m crocodile (the carcass was gone the next day). A an adult Water Python (*Liasis fuscus*) carcass with crocodile teeth puncture marks was also found cached on a snag in water (Fig. 2; D. Steer, pers. comm.). The snake was gone the next day. A Freshwater Crocodile (*Crocodylus johnstoni*) was found cached on a snag in water. The carcass had clear crocodile bite marks on its body and was attended by a 2.5 m *C. porosus*. The next day the carcass was half its previous size, missing the head and two limbs. The single fish cache was a ~1 m long Bull Shark (*Carcharhinus leucas*) found on a riverbank in 2001. A 4.5 m crocodile was observed several times at this exact location, which was a flat, muddy area with abundant cover provided by a fallen tree. The single bird cache was a Great-billed Heron (*Ardea*

sumatrana) found on a riverbank and attended by a 4 m crocodile in 2006. The crocodile was sighted at the same location the next day, but the cache was gone.

Prey caching by carnivores often occurs when predators kill prey too large to consume in one feeding bout (McDonald 1976; Smith and Reichman 1984). For example, Bobcats (*Lynx rufus*) cache White-tailed Deer (*Odocoileus virginianus*) and return to the carcass for further feeding (Labisky and Boulay 1998; McCord 1974). Similarly, *C. porosus* apparently cached and recovered a wallaby and a quoll (Fig. 1). It is important to distinguish between caching a carcass vs. simply returning to a carcass to feed. Although in a few cases floating carcasses could have lodged themselves against snags, many were clearly placed above, or partly above water (Table 1; Fig. 1; Fig. 2). Thus, at least some *C. porosus* kills were manipulated, presumably to facilitate further feeding and reduce the probability of competition. It is likely that other crocodilian species cache their food, especially large species and those known to capture prey too large to consume in one feeding bout. I could find no published reports of prey caching in crocodiles other than the report by Webb and Manolis (1989) that *C. porosus* will cache prey underwater or in mangroves. However, there have been a number of unpublished observations of individual *C. porosus* attending their kills. For example, in 2002 a *C. porosus* killed a tourist in a billabong in northern Australia, and authorities discovered the body later that night ~2 km from the attack site with the crocodile in attendance (C. Manolis, pers. comm.). In addition

TABLE 1. Prey caches of *Crocodylus porosus* discovered on the Daly River, Northern Territory, Australia, during the dry season.

Prey item	N	Location
Agile Wallaby (*Macropus agilis*)	28	water (20), riverbank (8)
Feral Water Buffalo (*Bubalus bubalis*)	2	against snag in water
Feral Pig (*Sus scrofa*)	1	snag just above water
Northern Quoll (*Dasyurus hallicatus*)	1	riverbank
Black-headed Python (*Aspidites melanocephalus*)	1	riverbank
Water Python (*Liasis fuscus*)	1	snag in water
Pig-nosed Turtle (*Carettochelys insculpta*)	1	snag just above water
Freshwater Crocodile (*Crocodylus johnstoni*)	1	snag in water
Bull Shark (*Carcharhinus leucas*)	1	riverbank
Great-billed Heron (*Ardea sumatrana*)	1	riverbank

FIG. 1. Agile Wallabies (*Macropus agilis*) cached by Saltwater Crocodiles (*Crocodylus porosus*). Top: A headless wallaby carcass cached on the riverbank. Bottom: Wallaby cache retrieved by a crocodile.

FIG. 2. Top: A Northern Quoll (*Dasyurus hallicatus*) cached on a riverbank is retrieved by a crocodile. Bottom: A Water Python (*Liasis fuscus*) cached on a snag in water by a crocodile. Note the puncture marks inflicted by the crocodile.

to those reported in Table 1, numerous additional wallabies were found floating down the river, of which most showed signs of crocodile attacks, including missing heads, front limbs, or injuries to the head and neck (see also Doody et al. 2007). In an unrecorded number of instances the carcasses were attended by a crocodile. I could not accurately determine the proportion of caches with a crocodile in attendance because our approach via motorboat often caused the crocodiles to submerge before being sighted (pers. obs.). However, in three cases we observed crocodiles towing wallaby carcasses across the river, although these particular carcasses were not known to be cached. There is currently no evidence that crocodiles defend their caches against scavengers, but this occurs in other carnivores known to cache (Smith and Reichman 1984).

Prey caching is sometimes associated with 'surplus killing', whereby a satiated predator makes another kill (DelGuidice 1998; Kruuk, 1972; Oksanen et al. 1985). In this case prey size is not necessarily important, but recent feeding leads to 'killing on a full stomach'. This appears to be the case with my observations of the quoll cache. This kill was unlikely to be too large for the crocodile to consume (Fig. 1), but the crocodile had apparently taken a wallaby two nights before the cache was found (pers. obs.).

Above-water caching has not been reported for crocodiles, but 12 of the 38 caches I found were above water (Table 1). Why cache above water, when more effort would generally be required to cache there? Smith and Reichman (1984) contend that the defensibility of the cache should be the primary consideration in the decision of where to cache, and some carnivores are known to defend their caches (e.g., Kim et al. 2005). Crocodiles may have learned to cache above water to avoid losing carcasses that are stolen, eaten, or incidentally dislodged by scavengers. We frequently found wallaby carcasses floating down the river that were previously attached to snags, or floating but lodged against the riverbank. These carcasses were apparently dislodged by other scavengers—most wallaby carcasses we observed were accompanied by scavenging pig-nosed turtles (pers. obs.), and water levels do not fluctuate during the dry season. The smaller, freshwater crocodiles were also attracted to the carcass, as were other *C. porosus* (pers. obs.). However, above-water caches are also scavenged. I have observed scavenging of above-water caches by monitor lizards (*Varanus panoptes*), Sea Eagles (*Haliaeetus luecogaster*), Wedge-tailed Eagles (*Aquila audax*), Whistling Kites (*Haliastur sphenurus*), Black Kites (*Milvus migrans*), and Grey Goshawks (*Accipiter novaehollandiae*). The diverse suite of scavengers at a site may influence a crocodile's decision of whether to cache prey in, or above water.

It is not surprising that Agile Wallabies were the most common prey cached by crocodiles. The species is abundant in the area, and thrives in nearby paddocks and open savannah. During the dry season free water is restricted to the river and a few permanent billabongs, bringing wallabies into contact with predatory crocodiles (Doody et al. 2007). Drinking wallabies exhibit a number of anti-predator behaviors, including increased apprehension and the excavation of drinking holes in the sand just out of reach of crocodiles (Doody et al. 2007; Steer 2007). There are a few anecdotal reports of wallabies or kangaroos falling prey to *C. porosus* (Pye 1976; Shield 1994). Those findings, combined with the present observations, indicate that agile wallabies are a significant prey item for *C. porosus*, at least during the dry season on the Daly River.

In summary, observations herein of crocodiles retrieving carcasses, combined with evidence that the prey were initially killed by crocodiles and manipulated thereafter, offer strong indirect evidence for prey caching in *C. porosus*. Although it is possible that these prey were killed by one crocodile and retrieved by another, in some instances the carcasses showed clear signs of being cached there by a crocodile. Caches are sometimes attended, but cache defense is unknown. I agree with Webb and Manolis (1989) that the commonly evoked idea that prey is cached because crocodiles prefer decomposed flesh over fresh kills is an unlikely explanation (see also Shield 1994). Indeed, predators may prefer fresh kills; some caching predators exhibit behaviors that may inhibit microbial action, such as burying, drying, and covering with 'antiseptic' sphagnum (Michener 2000; reviewed in Smith and Reichman 1984). It is more likely that large prey are cached due to constraints imposed by stomach size in the predator (about the size of a soccer ball in an adult *C. porosus*; Webb and Manolis 1989). However, evidence of latency to cache retrieval relative to decomposition rates is needed to determine why crocodiles cache their prey. Further research is also required on the potential defense of caches, their relative importance to energy uptake, and the relative costs to caching above water vs. in the water by *C. porosus*. Data from other crocodilians are also needed to evaluate the generality of the behavior in this group.

Acknowledgments.—I thank C. Manolis and R. Elsey for reviewing the manuscript, and for valuable information and relevant discussion. David Steer kindly provided his observation and photograph of a snake cache. R. Sims assisted in employing a camera trap. These observations were made possible by funding from Australian Geographic for predator-prey studies and from CSIRO and the Natural Heritage Trust for research on the impacts of cane toads on native predators. The research associated with the data herein complied with all animal care guidelines and was conducted under the appropriate permits from the Northern Territory government.

The Australian Lacelid, *Nyctimystes dayi*, is an endangered, stream-breeding hylid frog endemic to rainforests in the wet tropics of northeastern Queensland, Australia. During the 1990s, populations of *N. dayi* declined dramatically, with the species disappearing from all upland (>300 m) areas, where they were once common (Richards et al. 1993; Northern Queensland Threatened Frogs Recovery Team 2001; Trenerry et al. 1994). The proximate cause of these population declines and disappearances was the amphibian disease chytridiomycosis (Berger et al. 1998). This disease had similar effects on several other species sympatric with *N. dayi* (Berger et al. 1998). Habitat modification and fragmentation are also potential stressors for *N. dayi* populations, since approximately 20% of the wet tropics region has been clear cut since 1880 (Winter et al. 1987), and smaller-scale clearing still occurs in non-protected areas (e.g., for pastures, human settlement and associated infrastructure; Department of Natural Resources and Water 2007).

In order to make informed management decisions aimed at species conservation, it is necessary to have species-specific information on movement and habitat use, information that is lacking for the vast majority of amphibians (Johnson et al. 2007; Semlitsch and Bodie 2003; Trenham and Shaffer 2005). This is especially true for stream-breeding species such as *N. dayi*.

The study of *N. dayi* in the field has been hampered by several factors. First, the species is cryptic in both appearance and behaviour, and inhabits complex, densely vegetated habitats. Only males calling along streams in the breeding season are readily detectable. Second, males weigh less than 4 g, making them too small to track remotely using either radio-telemetry or harmonic direction finding (see Rowley and Alford 2007a), and females are rarely encountered (Czechura 1987; Hodgkison and Hero 2002), with male *N. dayi* 24 times more common than females along stream transects (Czechura 1987). As a result, the only information available on the ecology and habitat use of *N. dayi* is on males, and is derived from nocturnal surveys along streams or in riparian vegetation within 10 m of the stream (Czechura 1987; Hodgkison and Hero 2002).

Our objective was to track to track *N. dayi* females in the field, obtaining information on their movement and habitat use. The study was conducted at Tully Falls Forest Reserve (145.68ºE, 17.80ºS; 70 m elev.), in northern Queensland, Australia. Individuals were initially captured along a low-gradient stream containing pools, riffles, and a number of waterfalls. The stream was surrounded by relatively undisturbed rainforest vegetation, except for a sealed, two-lane road, which crosses the stream via a bridge approximately 20 m above the stream bed.

The study was conducted during the warm/wet season from 22 February to 8 March 2005 and the cool/dry season from 25 August to 8 September 2005. Tracking methodology followed that of Rowley and Alford (2007b). Each frog was captured by hand, weighed, fitted with radio transmitters (model BD-2NT; Holohil Systems Ltd., Ontario, Canada; weighing ca. 0.67 g including silicone tubing harness) *in situ* and released at point of capture within five minutes. Frogs did not carry more than 6% of their total body weight (the recommended maximum relative weight for an attached tag is 10% of the body weight; Richards et al. 1994). We tracked each frog using a HABIT Research HR2500 Osprey VHF Receiver (HABIT Research, Victoria, B.C., Canada), fitted with a three-element folding Yagi antenna (A.F. Antronics, Urbana, Illinois, USA).

The location of each frog was determined during two surveys per 24-h period, once during the day (0700–1900 h) and once at night (1900–0700 h) over the duration of the study. We established a marked transect along the stream edge to serve as a reference for frog locations, and when we located a frog, we recorded its three-dimensional position in meters as its location along the transect, its horizontal distance from the stream, and approximate elevation above stream. Distances were measured using tape measures, range finders and transect markers. If the frog was more than 20 m from the stream, distance from the stream was recorded to the nearest 5 m. We also recorded the environmental substrate frogs were using: bare ground, dry rock, leaf litter, vegetation, wood, on wet rock in stream, and under rock in stream.

TABLE 1. Movement patterns and habitat use of female *Nyctimystes dayi*. Values represent medians (and ranges) of data obtained using individual frogs as replicates.

Individual ID	Season	Total number of relocations	Percent of observations individuals moved between surveys	Distance moved between surveys (m)	Elevation above stream (m)		Horizontal distance from stream (m)	
					Diurnal	Nocturnal	Diurnal	Nocturnal
Frog 1	Cool/dry	24	60.9	8 (0–91.3)	3 (0–12)	3 (0–10)	8 (0–50)	3 (0–50)
Frog 2	Cool/dry	28	33.3	0 (0–27.1)	13 (0–20)	13 (0–20)	0 (0–3)	0 (0–3)
Frog 3	Cool/dry	15	64.3	4.2 (0–91.3)	0 (0–3)	0.75 (0–3)	0 (0–4)	0 (0–4)
Frog 4	Warm/wet	28	55.6	0 (0–20.6)	5 (0–10)	6 (0–10)	5 (0–20)	2.5 (0–10)
Frog 5	Warm/wet	19	66.7	4.7 (0–17.1)	5 (0–12)	5 (0–12)	4 (0–5)	5 (0–5)

We used individuals as replicates and compared summary statistics calculated for each animal, in order to avoid pseudoreplication and biasing our results by including more data on frogs that were located more often (Rowley and Alford 2007b). Due to obvious differences between the diurnal and nocturnal behavior of *Nyctimystes dayi*, we examined diurnal and nocturnal data on habitat use separately.

Five female *N. dayi* were tracked during the study period, three in the cool/dry season and two in the warm/wet season (Table 1). Our sample size was limited by the low availability of females for initial capture. We successfully relocated all frogs on every attempt, resulting in between 15–28 relocations per frog, and a total of 117 relocations for the species.

Tracked frogs moved to a new position between 33.3–66.7% of surveys (Table 1). The median distance moved between surveys (over ca. 12 h) ranged from 0–8 m, however two individuals moved more than 90 m between surveys (Table 1). The elevation of frogs above the stream during surveys varied from 0–20 m and their horizontal distance from the stream ranged from 0–50 m (Table 1). Individual movement patterns were variable; one frog remained within 5 m of the stream in both elevation and horizontal distance, while others moved extended distances vertically and horizontally from the stream for several days at a time (Fig. 1). No frogs were observed to have moved during the day. Tracked *N. dayi* were always relocated in rainforest. A single individual, "Frog 1," traversed the sealed, two-laned road twice during the study period.

During both diurnal and nocturnal observations, tracked frogs were most often located in vegetation (Table 2), typically in the canopy of large trees (>10 m height). When we were able to visually locate tracked frogs in the canopy, all were on the leaves of trees. During a single instance in which we opportunistically sighted a male *N. dayi* during the day, it was also located in vegetation, on leaves overhanging the stream. Frogs also spent up to several days at a time under rocks in the stream, and were occasionally observed during the night on wet rocks in the stream (Table 2). A single frog was observed on leaf litter during the study (Table 2).

We observed three of our tracked frogs in amplexus; two in the cool/dry season and one in the warm/wet season. "Frog 2" spent between 24–36 h in amplexus, on vegetation 1–2 m above the stream and 2 m in horizontal distance from the stream. "Frog 3" spent <12 h in amplexus on 3 m high vegetation, 4 m from the stream, and "Frog 5" was found in amplexus under a rock in the middle of the stream when we removed its transmitter at the end of the study.

Nyctimystes dayi females made relatively large (up to 50 m), extended journeys away from streams, spent a high proportion of their time in canopy vegetation, and were always observed in rainforest. Similar behavior has been recorded in females of the sympatric hylid *Litoria genimaculata* (Rowley and Alford 2007b). Although we did not track male *N. dayi*, due to their small size, we can make predictions about their behavior, based on the behavior of females. First, it is likely that the frequency and distance of movements in male *N. dayi* is lower than for females, as it is in many species, especially when males are smaller in size than females (Bartelt et al. 2004; Bellis 1965; Johnson et al.

TABLE 2. Substrate use of female *Nyctimystes dayi*. Values represent proportions of observations each frog was on each substrate type during diurnal and nocturnal surveys.

Individual ID	Season	Nocturnal				Diurnal			
		Vegetation	Under rock in stream	Leaf litter	On wet rock in stream	Vegetation	Under rock in stream	Leaf litter	On wet rock in stream
Frog 1	Cool/dry	0.73	0.18	0.09	0	0.69	0.23	0	0.08
Frog 2	Cool/dry	0.77	0.23	0	0	0.8	0.13	0	0.07
Frog 3	Cool/dry	0.29	0.71	0	0	0.5	0.5	0	0
Frog 4	Warm/wet	0.85	0.15	0	0	0.87	0	0	0.13
Frog 5	Warm/wet	0.78	0.22	0	0	0.8	0.1	0	0.1

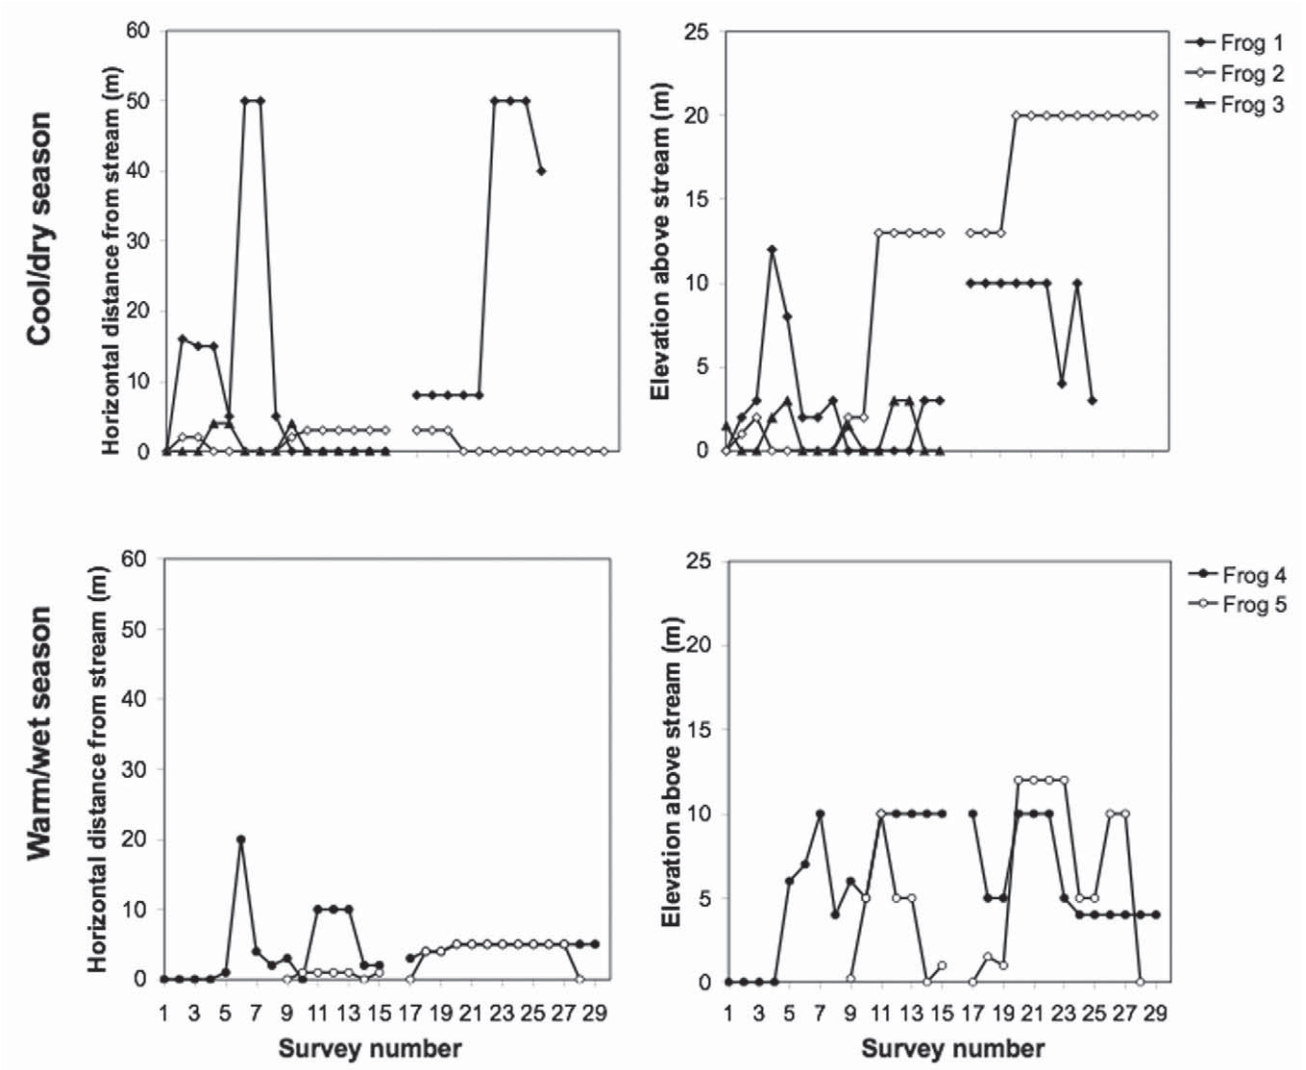

FIG. 1. Individual movement patterns of female *Nyctimystes dayi* during the cool/dry and warm/wet seasons. Values represent position of single frogs in terms of horizontal distance from stream (m) and elevation above stream (m) during successive surveys. Even numbered surveys represent diurnal surveys and odd numbered surveys represent nocturnal surveys.

2007; Miaud et al. 2000; Muths 2003; Ovaska 1992; Rowley and Alford 2007b). It is also likely that male *N. dayi* are more stream-restricted, especially considering their high relative abundance along streams, fidelity to calling-sites along streams (Hodgkison and Hero 2002; Rowley and Alford, unpubl. data), and inter-male aggression (Rowley 2007) during the breeding season.

Results of this study have important consequences for population censuses of *N. dayi* using techniques such as mark-recapture. The large movements of *N. dayi* both along and away from streams are likely to make it difficult to distinguish between mortality and emigration from fixed sites, an issue previously recognized for several other amphibian species (Rowley and Alford 2007b; Schmidt et al. 2007). In addition, it is likely that the high relative abundance of male *N. dayi* encountered during population surveys is simply a reflection of greater detectibility, with females spending large proportions of time farther away from the stream in terms of both horizontal distance and in elevation. This is probably exacerbated by the cryptic behavior of females. When they were adjacent to streams at night, they were often concealed from sight from the stream itself, and would have remained undetected had they not been fitted with tracking devices.

As *N. dayi* were always observed in rainforest, and used habitat at relatively large distances from streams, management actions aimed at conserving the species should maintain terrestrial vegetation buffer zones along streams and habitat corridors between streams. Although a single *N. dayi* successfully traversed a sealed road during the study, we do not know how common these movements are, whether male *N. dayi* are capable of traversing such potential barriers, and how great the risk presented by such traversals is. Until further research is carried out, it should be assumed that roads and other habitat disturbances are barriers to movement for *N. dayi*.

Acknowledgments.—This research was supported by funding from the Australian Geographic Society, the Society for the Study of Amphibian and Reptiles, the Peter Rankin Trust Fund for Herpetology, the Australian Government Department of Environment and Heritage, and from US National Science Foundation Integrated Research Challenges in Environmental Biology grant DEB-0213851, and was carried out under Scientific Purposes Permits issued by the Queensland Parks and Wildlife Service (WISP01715204 and WITK01715604) as approved by the James Cook University Animal Care and Ethics Committee (A863). JJLR was

supported by an Australian Postgraduate Research Scholarship. Thanks to many volunteers for assistance in the field, Stanwell Corporation Ltd. and all at Kareeya Hydro Power Station for accommodation and to R. Puschendorf for helpful comments on earlier drafts of the manuscript.

Microsatellites are a powerful set of highly variable molecular markers gaining widespread use in population genetics (Avise 2004) and increasingly in studies with a conservation focus (e.g., Beaumont and Bruford 1999; Jehle and Arntzen 2002). However, one drawback of microsatellites is that the development of these markers for use *de novo* typically involves the costly and time-consuming process of creating a genomic library, isolating microsatellite-containing clones, designing primers for the loci, and then optimizing the primers (Selkoe and Toonen 2006). Fortunately, the priming sites within the flanking sequences of microsatellite loci are sometimes conserved across species (e.g., Engel et al. 1996; Holman et al. 2005; Primmer et al. 1996; Primmer et al. 2005; Rico et al. 1996), including turtles (FitzSimmons et al. 1995). This allows the primers designed for one species (the focal species; Hutter et al. 1998) to successfully amplify loci in other species. In fact, many authors routinely test novel microsatellite loci on closely related species, usually within the same genus.

Turtles are considered one of the most endangered animal taxa, with 129 of the 205 species assessed by the World Conservation Union (IUCN) listed as critically endangered, endangered or vulnerable (http://www.iucnredlist.org/info/tables/table4a; accessed 27 May 2007). Genetic studies are playing an increasing role in the conservation of chelonians including the use of microsatellites, either alone (Pearse et al. 2006; Roberts et al. 2005; Schwartz and Karl 2005) or in combination with other genetic markers (Bowen et al. 2005; Sites et al. 1999). Interest in genetic studies of several species within the family Emydidae has been indicated by the recent publication of papers describing microsatellite loci for the Diamondback Terrapin (*Malaclemys*

terrapin; Hauswaldt and Glenn 2003), the Bog Turtle (*Glyptemys muhlenbergii*; King and Julian 2004) and the Blanding's Turtle (*Emydoidea blandingii*; Libants et al. 2004; Osentoski et al. 2002).

The imperiled nature of members of the genus *Graptemys* (family Emydidae) makes the use of genetic studies increasingly important. The genus *Graptemys* has a broad distribution across North America, but seven of twelve species in the genus are endemic to specific drainages east of the Mississippi River along the northern coast of the Gulf of Mexico (Ernst et al. 1994). Presumably this complex evolutionary history is the product of the fluctuating sea levels in the Gulf of Mexico during the Pleistocene (Lamb et al. 1994; Lovich and McCoy 1992; Wood 1977). Like many freshwater species, this genus appears to be extremely sensitive to human modifications and perturbations of the river and surrounding habitats (reviewed by Bulhmann and Gibbons 1997; Moll and Moll 2004).

The combination of such restricted distributions and apparent recent population declines has led to the listing of six species of *Graptemys* as either imperiled (G2) or vulnerable (G3) (NatureServe 2006). Two of the coastal species, *G. flavimaculata* and *G. oculifera*, have state endangered and federally threatened status (U.S. Fish and Wildlife Service 1988 and 1993). Furthermore, *G. barbouri*, *G. ernsti*, *G. nigrinoda nigrinoda*, *G. nigrinoda delticola*, and *G. pulchra* (all coastal species) are considered state protected in Alabama (Alabama Natural Heritage Program 2006). *Graptemys nigrinoda nigrinoda* is also considered state endangered in Mississippi (Mississippi Natural Heritage Program 2002). Developing effective management and recovery plans has been complicated by a general paucity of ecological information for *Graptemys* species (Bulhmann and Gibbons 1997), although there is a growing body of literature for *G. flavimaculata* (Horne et al. 2003; Jones 1996; Lindeman 1998; Shelby et al. 2000; Shelby and Mendonça 2001) and *G. oculifera* (Jones 2006; Jones and Hartfield 1995; U.S. Fish and Wildlife Service 1988). However, no published studies of genetic variation and population structure in the context of conservation issues exists for any of the *Graptemys* species. The goal of this project was to identify a suite of previously published microsatellite loci that would be useful for population and conservation genetic studies of *G. gibbonsi*, *G. flavimaculata*, and *G. oculifera*. Given the potential for cross-species amplification of microsatellite loci among related species, the loci we tested were selected from those developed for species within the family Emydidae. Loci found to be useful for the three *Graptemys* species in this study would also likely be useful for other members of the genus as well.

TABLE 1. Microsatellite loci tested in this study along with the repeat motif and optimal annealing temperature for each locus that was successfully amplified. Loci that were not successfully or reliably amplified are indicated by a –.

From April 2005 to November 2006 turtles were collected using basking traps or by hand during periods of low flow. *Graptemys gibbonsi* was collected from the Chickasawhay River (Pascagoula drainage) at Leakesville, Mississippi. *Graptemys flavimaculata* was collected from the Leaf River (Pascagoula drainage) north of Hattiesburg, Mississippi. *Graptemys oculifera* was collected from the Pearl River at Columbia, Mississippi. Approximately 1 mL of blood was drawn from the coccygeal vein using a heparinized 26.5-gauge needle and a 1 mL syringe. All individuals were released at the site of capture following sample collection. Samples were stored on ice for 4–6 h while in the field, centrifuged to separate plasma and blood cells and then stored at –20°C. All collections were made under permits from the Mississippi Department of Wildlife, Fisheries and Parks.

We selected a total of 21 loci for testing in *G. flavimaculata*, *G. oculifera* and *G. gibbonsi* (Table 1). All six loci for *Malaclemys terrapin* (Hauswaldt and Glenn 2003) were tested since each suc-

TABLE 2. Characteristics of the 21 microsatellite loci as reported for the focal species or as observed in the *Graptemys* species tested in this study: size range of alleles (in base pairs), the number of alleles (N_a) for each locus, and the observed and expected heterozygosity (H_O/H_E). NA means no amplification, and NR means not resolved. The number (N) of individuals tested for the focal species and each species of *Graptemys* is also reported.

cessfully amplified in *Chrysemys picta*. Two loci from each of the *Emydoidea blandingii* papers were also chosen based on their broad applicability in the species tested or the degree of polymorphism in *C. picta*. From Osentoski et al. (2002) we selected Eb15 and Eb17, and from Libants et al. (2004) we selected BTCA7 and BTGA3. Twenty–seven loci were reported for *Glyptemys muhlenbergii* (King and Julian 2004), and thirteen of these amplified in *Graptemys geographica*. We tested all but *Gmu*A18 and *Gmu*D89, since only a few alleles were reported in *G. geographica*.

Total genomic DNA was extracted with the DNeasy Tissue Kit (QIAGEN Inc.). Although heparin can sometimes have an inhibitory effect on the polymerase chain reaction (Beutler et al. 1990), this extraction method yielded good quality DNA that amplified well for most individuals. Amplifications were conducted in a total volume of either 12.5 µl or 25 µl using 50 mM KCl, 10 mM Tris-HCl (pH 8.3), 0.01% gelatin, 200 µM dNTPs, 2 mM $MgCl_2$ (4 mM for TerpSH3 & TerpSH7 and 1.5 mM for TerpSH8 in *G. oculifera*) 0.5 units of *Taq* polymerase (Promega Co.), 0.3 µM of the M13 tailed forward primer (Boutin-Ganache et al. 2001), 0.3 µM of the reverse primer, 0.1 µM of the labeled M13 primer (LICOR Co.), 20–150 ng of template DNA, and water to the final volume. PCR cycling conditions consisted of an initial denaturing step of 94°C for 2 min followed by 35 cycles of 30 sec at 94°C, 1 min at 52–60°C, and 1 min at 72°C. A final elongation step of 10 min at 72°C ended the cycle. Locus specific annealing temperatures are provided in Table 1. Microsatellite alleles were visualized on acrylamide gels using a LICOR 4200 DNA analyzer and scored using Gene Imag-IR v. 3.55 (LICOR Co.). We tested 20–34 individuals per species (Table 2). For polymorphic loci, summary statistics were generated using GENALEX 6 (Peakall and Smouse 2005). Tests for Hardy-Weinberg equilibrium and linkage disequilibrium were both conducted using randomization tests implemented in GENEPOP v 3.3 (Raymond and Rousset 1995). Statistical significance was adjusted using sequential Bonferrroni procedures (Rice 1989) for all multiple tests. We performed statistical comparisons of several properties of each locus (number of alleles, expected heterozygosity levels, smallest allele size, and largest allele size) to determine if the values for our study species were different from those reported for the focal species, and whether there were differences among our study species. To do this, we used one-factor analyses of variance, and for tests that showed a significant difference among the four groups we also performed post–hoc comparisons (Tukey's HSD) to test for differences between each pair (SAS Institute 2002). All analyses were performed using JMP 5.0 software.

Eighteen loci were reliably amplified in *G. gibbonsi*, and 16 loci were amplified in both *G. flavimaculata* and *G. oculifera* (Table 2). Of these loci, 15 were polymorphic in *G. gibbonsi*, 12 were polymorphic in *G. flavimaculata* and 11 loci were polymorphic in *G. oculifera*, with 2–13 alleles per locus per species. Two other loci (TerpSH3 and *Gmu*D87) amplified inconsistently in *G. flavimaculata* but appeared to be polymorphic and may yet prove useful after further optimization. Observed heterozygosity values ranged widely across species with values of 0.029–1.0, however most loci exhibited observed heterozygosity values greater than 0.500 (Table 2). No loci exhibited significant departure from Hardy-Weinberg equilibrium expectations or demonstrated linkage disequilibrium after applying a Bonferroni correction.

A common observation in studies testing cross-species amplification of microsatellite loci is that alleles are typically longer and more numerous in the focal species (e.g., Ellegren et al. 1995; FitzSimmons et al. 1995). Hutter et al. (1998) tested two hypotheses for this observation by performing a reciprocal test of microsatellite loci designed for two species of *Drosophila*. They found no difference in mean PCR fragment length, but there was greater variation in the focal species as measured by the number of alleles and expected heterozygosity. The statistical tests of our data revealed the same pattern. We found no significant differences among groups in length of the largest ($F = 0.877$; $df = 3,66$; $P = 0.458$) and smallest ($F = 0.274$; $df = 3,66$; $P = 0.844$) alleles. Reduced genetic variability was observed compared to the focal species. The number of alleles differed significantly among the focal and study species ($F = 6.73$; $df = 3,80$; $P = 0.0004$), and post-hoc comparisons showed that this was due to significantly higher numbers of alleles in the focal species than in the three study species. Number of alleles did not differ among the three *Graptemys* species. Likewise, expected heterozygosity values differed significantly among the four groups ($F = 4.65$; $df = 3,65$; $P = 0.005$), and post-hoc comparisons showed that values for all three *Graptemys* species were significantly smaller than those reported in the focal species. Heterozygosity levels did not differ among the three study species. Differences in sample sizes and the geographical range of samples are unlikely to account for the higher genetic variability in the focal species. Only Libants et al. (2004) sampled a large number of individuals from a broad geographic range. Our samples sizes (Table 2) were comparable to, or larger than, all of the other studies.

We have identified a set of microsatellite loci designed for species in the Emydidae that amplify in *G. gibbonsi*, *G. flavimaculata*, and *G. oculifera*. Somewhat reduced levels of genetic variability compared to the focal species does not appear to affect their usefulness as a conservation genetic tool. We have already employed these loci to document genetic differentiation between *G. gibbonsi* populations from the Pearl and Pascagoula Rivers (unpublished data). Our lab is also using these loci to measure connectivity among populations of *G. flavimaculata* within the mainstem Pascagoula River and its tributaries. The loci identified here (Table 2) may likewise prove useful in population genetics studies of other *Graptemys* species or even other species within the Emydidae.

Acknowledgments.—This research was funded by the Linnaeus Fund of the Chelonian Research Foundation and the Mississippi Department of Wildlife, Fisheries and Parks. Bob Jones (Mississippi Museum of Natural Science) and Lynn McCoy (Ward Bayou WMA Manager) assisted with many logistical aspects of this study. Also, this project could not have been completed without the help of the many that volunteered during the 2006 field season, including Danna Baxley, Tom Mohrman, Wilfredo Matamoros, John Spaeth, Justin Bishop, Brianna Zuber, Jake Schaefer, Shea Hammond, Austin Trousdale, Rick Burris, Melinda Miller-Butler, Rodney Felix, Caitlin Winters, Joe McGee, and Christine Selman. We would also like to thank Debbie Kreiser for invaluable editorial assistance. We thank Thomas McElroy and two anonymous reviewers for valuable comments that improved the quality of the manuscript. Collecting permits were provided by the Mississippi Department of Wildlife, Fisheries and Parks. All work was conducted in accordance with the appropriate institutional Animal Care guidelines. Order of the authors was determined by a coin toss.

Rapidly and accurately recording morphological characters from live lizards and snakes can be difficult, especially for small and/or venomous species. Ventral scale numbers and belly color patterns can be particularly difficult to record from live specimens, despite their importance for determining vertebral numbers (Alexander and Gans 1966; Kerfoot 1970), sexual dimorphism trends (Shine 1993), environmental conditions (Castellano et al. 1994), and correlations with body size, growth rate, and survivorship (Lindell et al. 1993).

Body length is another important part of any study of reptiles and amphibians (Measey et al. 2003) and snout–vent length (SVL) is the most commonly reported measure of linear body size (Fitch 1987). However, measuring the SVL of a snake can be problematic, especially for venomous species (Bertram and Larsen 2004).

Fitch (1987) stated that stretching a conscious snake to its full length for a SVL measurement may set back growth by several weeks. We observed similar results during a previous study of *Sinonatrix* snakes (Mao, unpubl.). Measurements from stretched snakes have been demonstrated to be significantly longer than measurements obtained by other methods (Bertram and Larsen 2004). In addition, squeeze boxes must be turned upside-down or used following the methods of Bertram and Larsen (2004) in order to obtain ventral characteristics or tail lengths.

Animals can be anesthetized in order to reduce injury to both study animals (e.g., tail autonomy) and investigators and to increase measurement precision (Blouin-Demers 2003; Setser 2007). However, anesthesia can increase potential risk of mortality, can be time consuming, and may be impractical when processing large numbers of individuals at one time (Setser 2007). Anesthesia also requires experienced personnel and specialized equipment, and is subject to legal constraints in many countries (Beaupre et al. 2004, Bennett 1999). In addition, anesthetized snakes can stretch considerably and do not necessarily provide more accurate measurements (Blouin-Demers 2003).

Schuett (1997) used photocopiers for measuring snakes, following Quinn and Jones' methods, and other researchers have used digital images from cameras (Measey et al. 2003; Perera and Pérez-Mellado 2004). In 1999, we developed a technique that employs a modified flatbed scanner to gather morphological data on *Sinonatrix annularis* and *Sinonatrix percarinata suriki*. This approach provided high quality images of ventral characteristics and body length of small to medium sized reptiles in a safe and rapid manner. Unlike large photocopiers, the scanner method can be used in the field by using a notebook PC with a scanner, while drawing power from a vehicle or generator. Compared to images taken with digital cameras, which often suffer from spherical distortion, the scanner provides a standardized platform that eliminates problematic biases such as angle and distance from the subject.

Materials and methods.—We originally used Hewlett Packard (HP) Scan Jet 3300C and Epson Perfection 1650 scanners, with maximum image resolution of 600 and 1650 dpi (dots per inch) respectively. We later used a HP Scanjet 4670 scanner because of its faster scanning speed, higher image quality, compact design, and lighter weight. A squeeze labyrinth (L × W × H = 30.3 × 22.3 × 5 cm) was designed to keep the body of the animal being scanned extended (Fig. 1). To prevent the subjects from moving while being scanned, the labyrinth has a plastic cover, onto which six strips of sponge are glued (each sponge being L×W×H = 20 × 4.2 × 5.2 cm, respectively). Larger lizards like *Plestiodon elegans* can be placed in the labyrinth, while lizards such as geckoes or the brown anole (*Norops sagrei*), as well as very small snakes, can be scanned by manually restraining the animal under a white cloth on top of the scanner. Very small characters such as the enlarged post-cloacal scales of male *N. sagrei* can be scanned by selecting the area and scanning it at 200–300% with a resolution of 300–400 dpi. We saved all scanned images to both the computer's hard drive and to CD or DVD.

In addition to the two above *Sinonatrix* species, we tested the method on 16 additional snake species: *Amphiesma sauteri*, *A. stolatum*, *Bungarus m. multicinctus*, *Enhydris chinensis*, *E. plumbea*, *Elaphe c. carinata*, *Lycodon r. ruhstrati*, *Oligodon formosanus*, *Oreocryptophis porphyracea kawakamii*, *Pseudoxenodon s. stejnegeri*, *Ptyas korros*, *Rhabdophis tigrinus formosanus*, *Rhadinophis frenatum*, *Trimeresurus gracilis*, *Viridovipera stejnegeri stejnegeri*, and *Xenochrophis piscator*. The largest and smallest snakes tested were 1350 mm SVL (adult *E. c. carinata*) and 90 mm SVL (neonatal *E. plumbea*), respectively. We also tested the method on 12 lizard species: *Eutropis longicaudata*, *Gekko hokouensis*, *Hemidactylus bowringii*, *H. frenatus*, *H. stejnegeri*, *Japalura swinhonis*, *N. sagrei*, *P. elegans*, *Sphenomorphus indicus*, *Takydromus formosanus*, *T. kuehnei*, and *T. stejnegeri*. The largest

FIG. 1. The scanner platform module (the main figure) from left to right clockwise; the PC notebook, cover glued with six sponge strips, the white labyrinth with one transparent side for animal observations, and a HP-4670 scanner. The upper right insert is the ventral image of an *Enhydris chinensis* with a tag number, indicating the collection and measurement data.

and smallest lizards tested were 120 mm SVL (*E. longicaudata*) and 18.5 mm SVL (neonatal *T. formosanus*), respectively.

To examine the accuracy and precision of the proposed method, we accumulated the body axis measurements (e.g., SVL, and tail length) of a single adult male *X. piscator* by using the following methods: 1) conscious—stretching the snake and directly measuring it by tape ruler—repeated five times; 2) scanning the snake with the HP-3300C, at 150 and 200 dpi resolutions, and measuring those lengths with a digital map-reader on a full size printout and directly from the screen by using GIS software—repeated five times; 3) same as no. 2 but using the HP-4670 as scanner platform at 200 and 600 dpi resolutions; 4) anesthetizing the snake and measuring once with a tape ruler.

Results.—We compared the measurements from the anesthetized snake against the other nine treatments (Table 1; based on the precision study results of Blouin-Demers [2003] and Setser [2007] this measurement was considered the standard value). Both the standard value and measurements from the stretched conscious snake resulted in longer measurements for total length (TL; ca. 4.2% longer) and SVL (ca. 6.2% longer) when compared to measurements from scanned images, irrespective of being calculated by map-reader or GIS software. In addition, most measurements from images scanned at 150, 200, and 600 dpi resolutions, and measured with the map-reader, were significantly smaller that the standard value of the snake length, especially for the images acquired with the HP-4670 scanner. Of the tail length measurements from different procedures, those acquired from scanner images were much closer to standard value than the ones from the stretched conscious snake. Although the TL measurements from stretched conscious snakes appeared to be very similar to that of the standard measurement, it resulted in a longer Tail-L and a relatively shorter SVL compared to the anesthetized snake (Table 1).

Most ventral characters can be easily counted from images on the computer screen. Unclear or small characters can be seen and counted after being magnified. Between 1999 and 2005 more than 400 different images have been recorded from *E. chinensis*, *E. plumbea*, *S. annularis*, *S. percarinata suriki*, and *X. piscator* for population monitoring. Ventral characters, including ventral scale number, gular region (Dowling 1951), subcaudals, chin-shield, and anal plate have been successfully scanned from every live snake, and we have successfully used ventral color patterns to identify individual snakes.

The scanned image also provides a record of the ventral markings and coloration. Ventral images of lizards scanned at a resolution of 300–600 dpi provides several additional characters in so far as the shape and number of the infra-labial scales, subdigital scales, posterior anal scales, tail-margin structure and, if present, groin

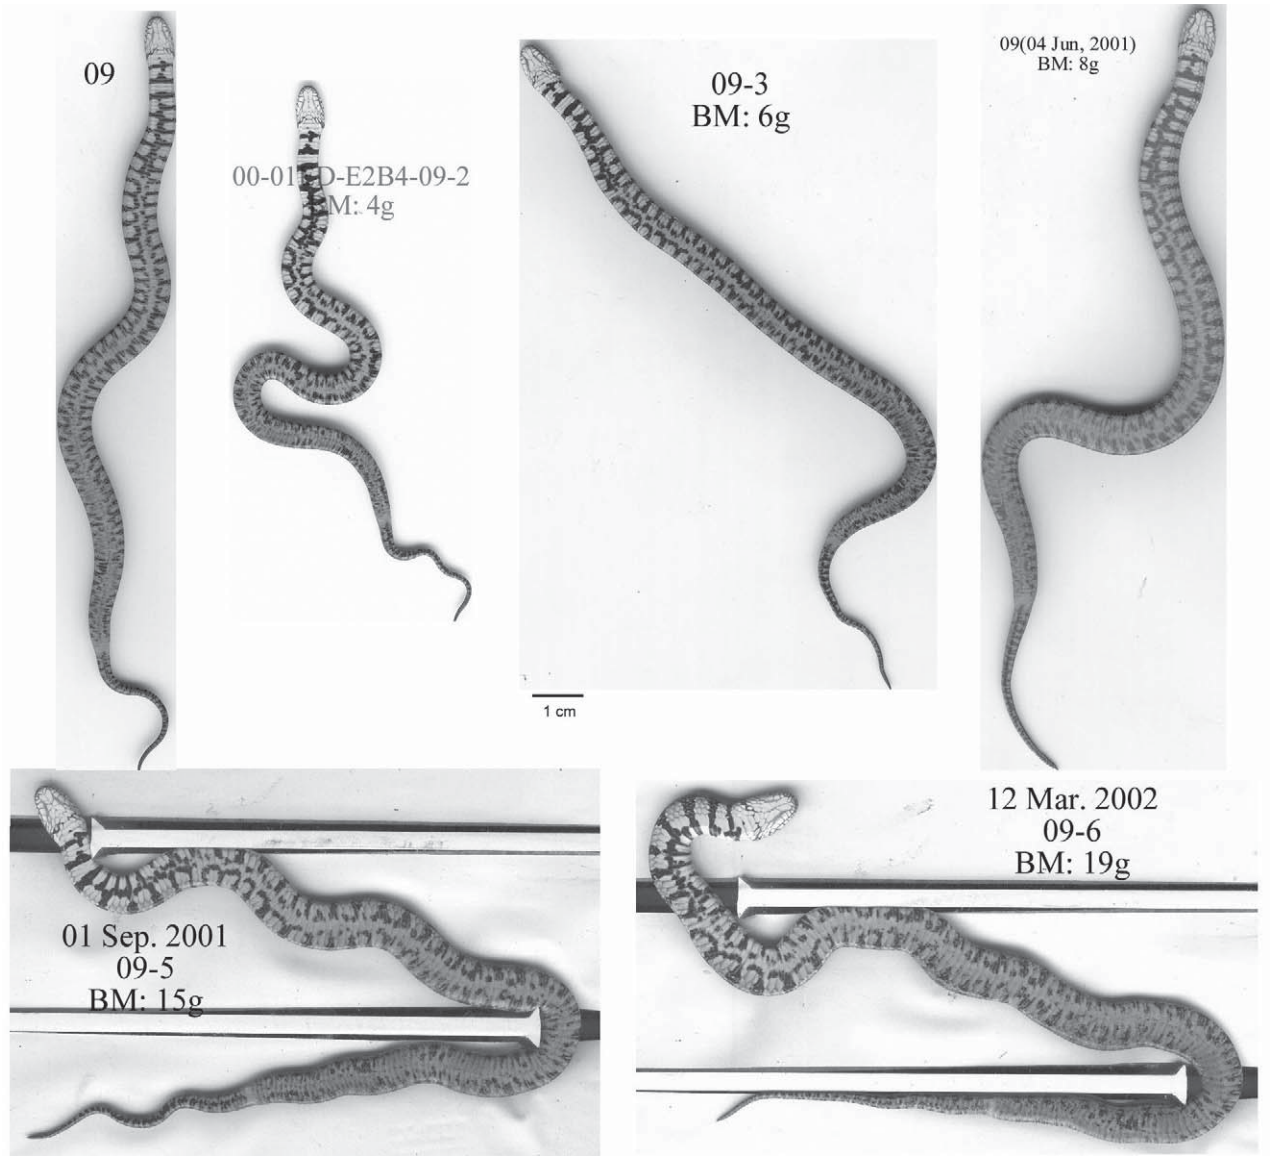

FIG. 2. The monitored ventral pattern and growth of a *Sinonatrix annularis* newborn over an 18 month period; (left to right, top to bottom) new born, 3 months old, 6 months old, 9 months old, 12 months old and 18 months old.

pores.

Our method has already been utilized to great effect in our field and laboratory studies. In 2000 the growth rate of a litter of newborn *S. annularis* was regularly recorded with this method in a field enclosure in a semi-aquatic Cape-lily (*Crinum* sp.) paddy, Yangminshan, Taipei (Mao 2003). For a period of nearly two years the seven neonatal *S. annularis* individuals were scanned every three months (Fig. 2).

Discussion.—Setser (2007) explained at length the problems associated with stretching snakes during measuring procedures, and although our proposed method does overcome this, it has some considerations that should be taken into account. The snake should be extended in the labyrinth, with as little kinking as possible, since these may result in slightly shorter measurements. In addition, the length measurements determined by GIS software were slightly closer to the standard value (anesthesia snake measurement), when compared to map-reader calculations, which may be due to multiple causes. First, the scanner models employed different image collection devices; for example the HP-3300C acquired images by optical reflection while the HP-4670 uses CCD. The efficiency of these two devices will differ slightly, especially when the image is printed out on paper (HP technical support, Taipei, pers. comm.). Moreover, the length and distance on the image must be defined *a priori*, and some size rectification must be done by a length scale before GIS software measuring. This is not necessary with the printout measurements, but it must be taken into consideration that the snake's posture (coiled taut or loose) and anthropogenic operating biases may result in variation, especially when the map-reader must calculate the continually linear curves of a snake. However, a size rectification by verifying if the object size is 1:1 by checking certain length scales on the image (e.g., labyrinth trail width) can greatly reduce these problems, whether lengths are determined using software such as Image Tool (Measey et al. 2003), on the computer screen using GIS software (e.g., ArcView), or via a map-reader or proportional divider on a printout.

Natural markings were used in a Swedish *Natrix natrix* population (Carlström and Edelstam 1946) to identify individuals,

TABLE 1. Results of the length measurements taken from a male *Xenochrophis piscator* by four different methods and image resolutions. The asterisk indicates significant differences among the nine length measuring treatments compared to anesthesia of the snake (two tailed *t*-distribution test, P = 0.01, 4 df).

Input tool	Measuring method	TL in cm (mean ± SD)	t-value	SVL in cm (mean ± SD)	t-value	Tail-L in cm (mean ± SD)	t-value

and this method was also proposed for studies involving some lizards and amphibians (Ferner 1979). However, it had only limited applications for some species because this method was based on color pattern permutation. A snake "fingerprinting" digital system was developed by Hailey and Davies in 1985, and was based on a combination of natural markings and ventral scale blotch patterns, recorded by photographing *Natrix maura*. Photo identification has also been shown to have good potential as a non-invasive identification technique for some amphibians such as *Eurycea bislineata wilderae* (Bailey 2004). Digital cameras can be used for recording characteristics of individuals and could aid in taking various measurements (Measey et al. 2003; Perera and Pérez-Mellado 2004). Bender (2001) proposed the use of natural markings to identify individual reptiles, especially for the registration of pets. In our opinion, images of the ventral views of lizards and snakes from digital cameras may be out-of-focus or exhibit insufficient image quality if using the technique proposed by Bender (2001). Measey et al. (2003) also stated that the digital cameras are prone to un-repairable error in the field. During previous observations it was found that photographs could not always reflect a clear ventral pattern image of the snake, especially, when the individual being photographed was small or under conditions of multiple light sources (Mao and Norval, pers. obs.). In addition, there was the problem of restraining the snake in an upside-down position. Mertens (1995) used xerographic copies to recognize individual juvenile *Natrix natrix*, but bulky xerographic equipment is difficult to transport and is costly to acquire and maintain. Furthermore, when a large number of fingerprinting files are required for resources management purposes, locating the correct fingerprinting pattern from the huge number of images in the database can be a time consuming process. Although some of the commercially available software does not fully satisfy our requirements of image database sorting and comparison, it is our opinion that by incorporating the proposed scanner method with some commercial digital camera software (e.g., Visual Similarity Duplicate Image Finder), the process can be greatly simplified, and could be an invaluable tool in dealing with herpetological fieldwork involving identification of individual animals. We believe our proposed method not only aids in measuring small reptiles, but can also have broad application in population studies.

Acknowledgments.—Special thanks are extended to M.-C. Tu for making the *Trimeresurus gracilis* in his laboratory available for scanning trials, and to Y.-C. Lai, who assisted with the length measurements of snake images using GIS software (Arc View). We also express our gratitude to Nico van Loggerenberg for his comments and for proofreading this paper.

Reptiles maintain their body temperature (T_b) at or near a preferred level that is generally referred to as the thermoregulatory set-point range (T_{set}; Hertz et al. 1993). Knowledge of T_{set} is useful as an indicator of the T_b that an organism tries to achieve and maintain during thermoregulation (Angilletta and Werner 1998). Careful regulation of T_b increases the time spent at physiologically favorable temperatures (Huey et al. 1989). It is often assumed that T_{set} is the optimal temperature range since an animal would strive to maintain a T_b at which it performs and/or functions optimally (Bartholomew 1977).

Measuring T_{set} is significant in studies of ectotherms because it provides a yardstick against which field or operative temperatures (T_e) can be compared and the effects of environmental or physical conditions on thermal performances can be evaluated (Al-Johany and Al-Sadoon 1996; Van Damme et al. 1986). T_{set} is measured in the laboratory using thermal gradients or mosaics, which have been used in studies of thermal preferences in a wide variety of reptiles (e.g., see Al-Johany and Al-Sadoon 1996; Blouin-Demers et al. 2000; Firth and Belan 1998; Gvoždik and Castilla 2001; Patterson and Davies 1978; Stapley 2006; Tosini et al. 1995). While thermal gradients are useful in thermal studies on reptiles, thermal mosaics are preferable because they provide multiple thermal gradients and therefore create more choices for the reptile. Thermal gradients are generally constructed as a box with one end heated and the other end cooled creating a thermal gradient from one end to the other, which results in only one location for any particular temperature. In thermal mosaics, two opposite corners are heated and the other two corners are cooled, which establishes multiple gradients across the floor of the box. In a mosaic, the reptile is therefore able to choose among different areas that are the same temperature.

For semi-aquatic reptiles, the ability to regulate T_b within T_{set} may vary considerably between aquatic and terrestrial habitats. Water has a higher thermal inertia than air and is therefore more thermally stable than many terrestrial habitats. Although a terrestrial mosaic is useful in measuring T_{set} in a terrestrial environment, the thermoregulatory abilities and/or preferences of semi-aquatic reptiles in water may vary due to the different thermal properties of water. Owing to limitations with the design and construction of thermal mosaics, studies of thermal preference have been conducted primarily on terrestrial species.

Thermal preferences in fish are commonly measured using shuttleboxes. The shuttlebox usually consists of two chambers connected by a channel. The difference in the water temperature between the chambers is constant and the fish is able to move freely between the chambers. The temperature in the chambers is usually increased or decreased depending on whether the fish chooses the warmer or cooler chamber. The preferred temperature is measured as the actual chamber temperature (e.g., see Mortenson et al. 2007) or determined by the time spent in each chamber (e.g., see Larsson 2005). Thermal gradients are also used in some studies measuring thermal preferences in fish. These thermal gradients generally comprise a large box divided into zones or lanes with varying temperatures along the length of the box to create a temperature gradient (e.g., see Lafrance et al. 2005; Podrabsky et al. 2008). Tamplin (2006) successfully used an aquatic thermal gradient (similar to those used in fish studies) to investigate the thermal preferences of hatchling Wood Turtles (*Glyptemys insculpta*), but, to the best of our knowledge, there have been no studies of semi-aquatic or aquatic reptiles using an aquatic mosaic.

Here, we provide a description of a novel aquatic mosaic we successfully used in investigating thermal preferences in juvenile Yellow Anacondas (*Eunectes notaeus*; SVL 0.5–0.6 m, mass ca. 180 g; N = 8; McConnachie, Greene and Perrin, unpublished data) and Common Brown Water Snakes (*Lycodonomorphus rufulus*; SVL 0.4–0.6 m, mass ca. 60 g; N = 5; McConnachie and Perrin, unpubl. data).

The aquatic thermal mosaic (1.2 x 1.2 x 0.5 m) was constructed from 10 mm marine plywood with a transparent acrylic fitted lid. The plywood box was divided into 16 three dimensional (300 x 300 x 200 mm) compartments with 10 mm marine plywood partitions and the interior walls were coated with fiberglass. Each compartment contained an immersion heater (500 W – reconfigured to run at 250 W), earthing rod (for the safety of researcher and reptiles in case of a short circuit), temperature sensor and air stone (Fig. 1).

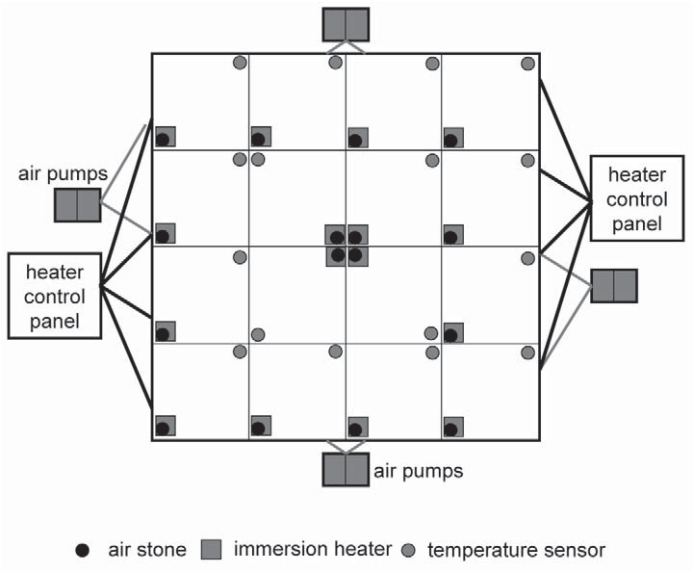

FIG. 1. Layout of the aquatic thermal mosaic. The immersion heater and temperature sensor were placed in opposite corners of compartments to ensure even heating of the water in each compartment.

Each immersion heater and corresponding temperature sensor was connected to a thermostat (-40–50ºC, resolution 0.1ºC) located in one of two control panels. Eight standard dual tube aquarium air pumps (Jumbo Jet 7800) powered the 16 air stones to circulate heated water. All wiring and tubing was glued and/or taped to the partitions or sides of the mosaic and each heater was enclosed in plastic mesh to avoid influencing or interfering with snake movement (Fig. 2). Each compartment was filled with water to within 5 mm of the top of the partitions and randomly assigned a temperature between 10ºC and 45ºC at 5ºC increments. We decided on a random placement of temperatures to create numerous gradients between the different compartments and to provide the snakes with as heterogeneous an environment as possible. The mosaic was set up in a constant environment (CE) room with T_a of 10ºC to maintain low temperatures and to encourage snakes to remain in the water. (Very little is known about Yellow Anacondas or Common Brown Water Snakes in the wild, but both occur in areas which experience environmental temperatures below freezing. A T_a of 10ºC is likely to be at the lower end of range of T_es usually available to both species in the wild.) The range of aquatic T_es available to the snakes (17-44ºC) was measured using 100 iButtons (Dallas Semiconductor, Texas) spread throughout the mosaic.

In order to avoid a build up of condensation on the acrylic lid of the aquatic mosaic, we raised each side of the lid to an angle of approximately 30º. A bracket was made for each side and the gap was covered in 30% shade cloth to allow moisture out, but keep snakes in. Although the modification resulted in some evaporative water loss, particularly from the warmer compartments, we were able to run a full trial (36 h; 12 h acclimation, 24 h recorded trial) without having to add water.

The design and construction of the aquatic thermal mosaic allowed us to establish the T_{set} for juvenile Yellow Anacondas (ca. 28ºC) and Common Brown Water Snakes (ca. 21ºC; calculated as the range of T_bs selected over the 24 h recorded trial; data from these experiments to be published elsewhere). Similar to a terrestrial thermal mosaic, the aquatic thermal mosaic provided multiple thermal gradients over a wide range of temperatures, which were easily adjusted. Because our mosaic allowed for such a wide range of temperatures, it should be suitable for determining T_{set} (and other thermal preference measurements) for species with different thermal requirements.

We encountered a variety of problems during construction and running of the aquatic mosaic. In the aquatic mosaic, snakes were observed resting on the partitions between compartments, with parts of their bodies in one or more compartments. Although completely aquatic species may spend all their time submerged in one compartment or another, semi-aquatic species can be expected to spend some time out of the water. Our compartments may have been too deep for the snakes to rest comfortably while submerged in the water. The snakes may also have preferred the support of the compartment wall because there were no resting points within the compartments. A stone or small branch submerged in each compartment would provide a shallower resting point within the compartment, which may encourage the snakes to remain in the compartment.

The immersion heaters we used initially were designed to heat water in coffee cups and often malfunctioned or burned out. While the immersion heaters were suitable for our study on juvenile Yellow Anacondas, they were replaced with 100 W aquarium heaters (Resun). The aquarium heaters were more stable and efficient and were used successfully for the study on Common Brown Water Snakes. The built-in temperature control mechanism was bypassed and each heater was controlled using the temperature sensors and controllers. The aquarium heaters proved superior to the immersion heaters, particularly because they can be more finely controlled. In addition, the original heaters in the middle four compartments could only be mounted in the centre of the mosaic. The aquarium heaters could be mounted identically in each compartment, which meant that each compartment was structured identically and was less likely to affect snakes' movements or preferences based on compartment structure. The original heaters also resulted in substantial amounts of evaporative water loss, particularly in the warmer compartments, and the snakes had a tendency to perch

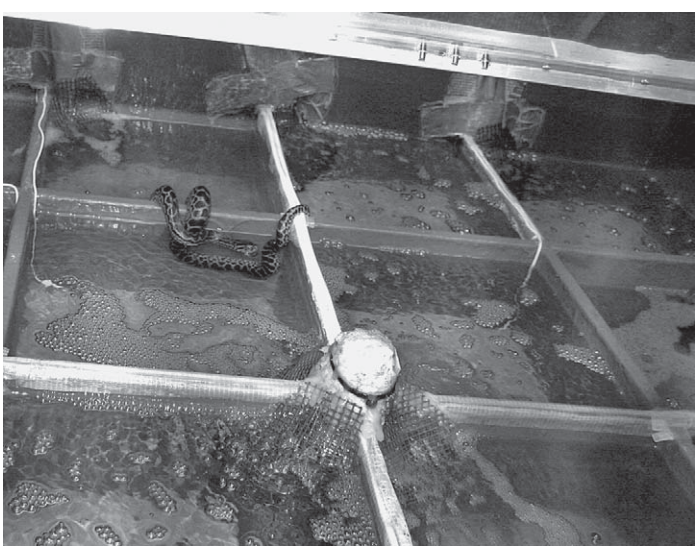

FIG. 2. Juvenile Yellow Anaconda (*Eunectes notaeus*) in the aquatic thermal mosaic. Wiring and tubing were glued and/or taped to the partitions or sides of the mosaic and each heater was enclosed in plastic mesh.

out of the water on the compartment partitions. Heating with the aquarium heaters resulted in less evaporative water loss, so the snakes tended to remain submerged instead of perching out of the water on the partitions.

Temperature in the aquatic thermal mosaic was easily adjusted using the temperature controllers. In addition, the temperature of the CE rooms where the mosaics were housed could also be adjusted. Adjusting both CE room and heater temperatures allow for a wide range of temperatures. Also, temperatures in individual compartments in the aquatic thermal mosaic could be individually controlled, so temperatures for compartments could be randomly or structurally organized. While we were able to maintain stable temperatures in most compartments, we were not able to maintain the lowest temperatures because warm compartments adjacent to coldest compartments often warmed them. There was no insulation between adjacent compartments other than the marine plywood partitions. Additional insulation may be necessary to maintain distinct temperature differences between compartments.

Overall, the aquatic thermal mosaic worked well for determining thermal preferences of juvenile Yellow Anacondas and Common Brown Water Snakes, and is suitable for use with other semi-aquatic reptile species. Despite the problems we experienced with the immersion heaters, they worked sufficiently to complete the Yellow Anaconda study, but the aquarium heaters used in the Common Brown Water Snake study are better suited. The ability to adjust the temperatures of both heating and cooling systems (directly through heaters or indirectly through changing T_a) suggests that the aquatic mosaic is suitable for use in studies on other aquatic and semi-aquatic snakes and potentially other aquatic and semi-aquatic ectotherms. Fine-tuning the mosaic for the requirements of each species will enhance the success of the apparatus while investigating thermoregulation in aquatic and semi-aquatic animals.

Acknowledgments.—We thank Martin Hampton, Alan Cullis, Guy Dewar and the staff of the University of KwaZulu-Natal Workshop and Electronics Department in Pietermaritzburg for their technical advice and expertise. Thanks also to Andrew McConnachie and anonymous reviewers for providing helpful comments and suggestions on the manuscript. All experimental procedures used were cleared by the Animal Ethics Committee of the University of KwaZulu-Natal.

SSAR Student Travel Awards — Call for Applications

Ten awards of US $400 each are available to students to help defray the cost of traveling to the 2009 Joint Meeting of Ichthyologists and Herpetologists (JMIH). An applicant for a travel award must be a student and a current member of SSAR, must not have previously received a travel award from SSAR, and must be the first author of a paper or poster to be presented at the 2009 JMIH. The application package must include: 1) a letter signed by his/her major advisor or department chair that states that he/she is not completely funded for travel from another source and, if the research is co-authored, that the work was primarily the product of the applicant; 2) a copy of the abstract that was submitted for either poster or oral presentation. The qualified applicants will be pooled and the winners will be drawn at random. Students from the immediate vicinity of the JMIH, as well as current members of the SSAR Travel Awards Committee, are excluded from applying for a travel award. Award checks will be disbursed at the SSAR Business Meeting to be held during the JMIH. Application materials are preferred in electronic form (either PDF or Microsoft Word) and should be sent to Matthew Venesky by 15 April 2009 (mvenesky@memphis.edu); however, hard copies can be mailed to Matthew Venesky, The University of Memphis, Department of Biology, Memphis TN USA, 38152. Hard copies sent via postal mail must be postmarked prior to 15 April 2009 to be considered.

For more information, contact: Cari-Ann Hickerson (chickerson@jcu.edu) or Matthew Venesky (mvenesky@memphis.edu).

Obvious risks are associated with measuring venomous snakes. Herpetologists have employed several methods for restraining venomous snakes while taking measurements, including, but not limited to holding the snake behind the head by hand, anesthesia, tubing, and squeeze boxes (Fitch 1987; King and Duvall 1984; Quinn and Jones 1974). The squeeze box method may be considered among the safest options because it does not require direct contact with the animal. Squeeze boxes generally consist of a wooden box with a foam insert that fits snuggly inside the box and a Plexiglas® sheet that fits inside the box on top of the foam insert (Quinn and Jones 1974). The clear sheet permits general morphological measurements such as snout-vent length (SVL) and tail length (TL) (Quinn and Jones 1974). However, the traditional squeeze box design only allows a dorsal view of the snake. Here we present a new variation on the traditional squeeze box design that permits both a dorsal and ventral view of the study animal.

Traditionally, tongs are used to place snakes between the Plexiglas® top and foam rubber base, permitting a safe estimation of snout-vent length from a dorsal view (Quinn and Jones 1974). Little has changed in the squeeze box design, although modifications have been made with lightweight materials for field use (Cross 2000). Our squeeze box design maintains the general shape of the traditional box. Size during construction will vary according to the animals being investigated. The sides are constructed of wood with a foam pad placed inside. In addition to a Plexiglas® top, our squeeze box also has a Plexiglas® bottom secured to the sides with screws (Fig. 1). Holes are drilled through the center of the opposing sides of the box allowing a dowel rod to pass across the top piece of the Plexiglas®, which locks the removable Plexiglas® lid in place while viewing the animal's venter. Large boxes may require holes on each side of the box and two dowel rods to ensure a secure hold on the animal. Holes are drilled at varying levels to allow for variation in the robustness of different species. In order to view the venter, the animal is placed in the box on top of the Plexiglas® bottom, with the foam pad and Plexiglas® lid placed on top of the animal. Therefore, the snake can be safely viewed from above, like the traditional box, and from below.

Some snake measurements depend on ventral markers, such as the cloacal vent, ventral pattern and scale counts. Using a traditional squeeze box to estimate ventral markers from a dorsal view may lead to significant error in measurements (Bertram and Larsen 2004). To compare measurements, the SVL of 10 watersnakes (*Nerodia fasciata*) were traced from both the ventral and dorsal views. Each trace was measured three times with a flexible tape measure and the means of the ventral and dorsal measurements were compared using a one-tailed paired t-test. Bertram and Larsen (2004) found the accuracy of this measuring method equal to more rigorous methods and with less stress to the animal. From the dorsal view, SVL was significantly overestimated relative to the ventral view ($\text{mean}_{\text{dorsal}} = 45.45$, $\text{mean}_{\text{ventral}} = 43.99$; d.f. = 9, $P = 0.0038$), and the average standard deviation was less for the ventral view ($SD_{\text{ventral}} = 0.231$, $SD_{\text{dorsal}} = 0.369$).

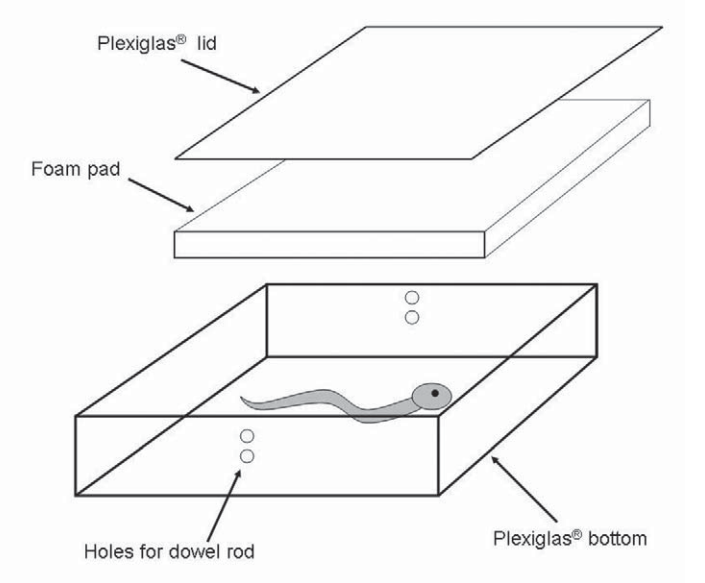

FIG. 1. Diagram showing the method for viewing the venter of snakes in the novel squeeze box.

With the use of the new squeeze box design, the dowel rod secures the lid at a chosen height, lightly squeezing the study snake between the Plexiglas® bottom and the foam insert. When turned over the snake remains in place, permitting confident measurements of SVL and TL. In addition to improved measurement accuracy, the new design allows a ventral view of the snake for photography or studies involving patterns or coloration. Further, with both dorsal and ventral views, scale counts can be taken safely on live individuals.

Acknowledgments.—We thank the Center for Ecology and Evolutionary Technology, the University of Louisiana at Lafayette Graduate Student Organization, C. Monteiro, and S. Peterson. We also thank K. Setser and one anonymous reviewer for comments on the manuscript.

AMPHIBIAN DISEASES

This section offers a timely outlet for streamlined presentation of research exploring the geographic distribution, host range, and impact of emerging amphibian pathogens, especially the amphibian chytrid fungus *Batrachochytrium dendrobatidis* (*Bd*) and ranaviruses. *Bd* is an emerging pathogen linked to mass mortality and declines of amphibians worldwide, yet Bd has also been detected in amphibians without disease. Ranaviruses also cause mass mortality, but have not yet been linked to large-scale declines. We know relatively little about their global distribution, host range, or impacts on host populations. To improve our understanding of the scope of this issue, we encourage submission of studies that illuminate the geographic distribution, host ranges, and impact of these pathogens on amphibian populations, including research on individual species or groups of species, wild or captive animals, native or non-native species, live animals or museum specimens, environmental samples, and, provided there is sufficient sampling[1], reports of non-detections.

We ask authors to: 1) restrict the Introduction of their paper to a **maximum** of two paragraphs to highlight the context of their study; 2) briefly include both field and laboratory Methods; 3) present Results in a Table, although a map might also be useful, and limited text; and 4) have a short discussion of a **maximum** of three paragraphs to touch upon key findings. Please include the following information in submissions as appropriate: coordinates and description of sampling areas (or please note if locations are extremely sensitive to reveal, and provide general area instead); species name(s) and life history stages examined, as well as other species present; whether samples were collected randomly or just from dead or moribund animals; date of specimen collection; evidence of unusual mortality; numbers of positive and negative samples; disposition of voucher specimens; name of collaborative laboratory or researcher conducting histological sections or PCR analyses; and names of cooperative land owners or land management agencies. We encourage researchers to conduct post-mortem examinations when possible to identify the cause of death when reporting mortalities. We aim to expedite the review and publication process! Please e-mail submissions directly to Associate Editor, Dr. Dede Olson: dedeolson@fs.fed.us.

[1]If a sample of 30 individuals of a particular life history stage of a particular species yields no positive results, and the diagnostic test is highly sensitive, one can conclude that the prevalence of infection is less than 10% with 95% confidence. With a sample of 10 an infection in one of four individuals could go undetected. We encourage researchers to collect sufficient samples that negative results are meaningful.

Grantham, Pennsylvania 17027, USA

Chytridiomycosis caused by the pathogenic fungus *Batrachochytrium dendrobatidis* (*Bd*) has been implicated as a cause for many widespread amphibian declines (Berger et al. 1998; Bosch et al. 2001; Briggs et al. 2005; Ron and Merino 2000; Skerratt et al. 2007). Amphibians of Central America have experienced substantial declines involving 30 genera and nine families (Young et al. 2001) and *Bd* has been implicated in a number of these declines (Lips et al. 2006). For example, about 50 percent of the amphibian species at Las Tablas, Costa Rica, have declined or disappeared apparently due to *Bd* infection (Lips et al. 2003). A more thorough understanding of the natural history and ecology of *Bd* is still needed, and knowledge of the geographic distribution of this fungal pathogen is important for biological conservation (Adams et al. 2007; Young et al. 2001). Recently described techniques allow for the rapid detection of *Bd* DNA from skin swabs (Boyle et al. 2004) and environmental water sources (Kirshtein et al. 2007; Walker et al. 2007). To gain insight into the spatial distribution of *Bd* within a neotropical cloud forest habitat we utilized water filtering and quantitative PCR techniques to: 1) determine the presence of *Bd* in lotic water sources at a site where historic die-offs were attributed to *Bd* mortalities; and 2) determine if *Bd* was present in water collected in arboreal, epiphytic bromeliads.

Methods.—Our study was conducted in the cloud forests of the Los Quetzales Preserve (8.876389°N, 82.547222°W, 2200 m elevation), a private land holding adjacent to Parque Nacional Volcan Barú, Chiriquí Province, Panamá. We used the US Geological Survey (USGS) Backcountry Chytrid-water Field Protocol (C. Anderson, pers. comm.), similar to that described by Kirshtein et al. (2007), to detect and quantify the presence of *Bd* zoospores in water between 4 and 7 January 2008. Using vinyl examination gloves, we processed one sterile water control, as well as samples from a headwater stream (N = 3) and bromeliads (N = 5). Zoospores in sampled water were trapped by using sterile 60 cc syringes with Leur-lok® ends to pump water through 0.22 µm Sterivex™-GP filters. The volume of pumped water necessary to nearly occlude each filter was recorded. Filters were rinsed with 50 ml of sterile buffered phosphate saline (Sigma-Aldrich P5368). Filters, with retained particulates, were preserved with 0.9 ml of cell lysis solution (Fisher Scientific FP2301320). Cell lysis accommodated sample storage under variable field temperatures until subsequent laboratory analysis (Kirshtein et al. 2007). Sterile Leur-lok® caps were used to seal filter inlets, while a hematocrit sealant was used for outlets of each Sterivex™ filter. All sample filters were labeled and sealed individually in plastic zippered bags.

Stream samples were obtained from a 1st-order tributary of Río Chiriquí Viejo. This permanent stream was ca. 1 m wide and maximum depth was approximately 0.1–0.3 m. Water clarity was high and the primary substrates were gravel and cobble, with small areas of sand and silt accumulation in low velocity pools and along stream edges. Stream temperature at the time of sampling was a mean of 13.1°C. There was little aquatic vegetation and only slight amounts of organic debris, with low levels of suspended and dissolved organic matter. During sample collection, the weather was overcast with a light drizzle and air temperature was 8.5°C. Water was collected from riffle zones near the stream margin at 25 m, 75 m and 125 m upstream from the river confluence. We filtered 4.0 L, 4.2 L and 4.0 L respectively (see Table 1). These quantities were roughly double the maximum filtered volumes from lentic waters reported by Kirshtein et al. (2007), owing to the lack of suspended material in the stream.

Bromeliads at heights of less than 1.75 m were sampled from the ground, while those located higher in the canopy (from 2 to 11 m) were accessed using both single and doubled rope techniques. Water was collected by pulling down exterior bromeliad leaves, re-

TABLE 1. Quantitative PCR analyses were used to detect the presence of the amphibian chytrid fungus *Batrachochytrium dendrobatidis* (*Bd*) in water samples collected from a first-order stream and from arboreal sources (bromeliads) at Los Quetzales Reserve, Guadalupe, Panamá, in 2008. *Bd* zoospore equivalents per liter are reported for each of two replicate samples analyzed (rep) and their means. NA = Not applicable; ND = Not detected.

leasing stored water from leaf axils. As water was released it was captured in clean, 3.78-L plastic zippered bags. Underlying leaves on one side of the bromeliad (the lowest side if the bromeliad was growing at an angle) were successively bent down releasing additional water that dripped off the leaf tip. Individual bromeliads were sampled by this method until sufficient water had been obtained for a filter sample (~1 L). The amount of water from each bromeliad varied due to varying water holding capacities of the plants. Approximately 25–50 ml of water was obtained from each bromeliad. Three of the arboreal bromeliad water samples contained water from multiple bromeliads, ranging from 7 to 17 plants, and from heights of <1 to 6 m off the ground (Table 1). Two arboreal water samples were from a single bromeliad each, at heights of 1.75 m and 11 m. Bromeliad water ranged in temperature from 12.0 to 13.9°C. The five bromeliad samples had filtered water volumes ranging from 25 to 160 ml (Table 1). Because of the large amount of suspended organic material, we let each sample settle at ambient temperatures (< 17°C) for 2–7 h before extracting water for filtering. The high organic content of bromeliad water resulted in rapid clogging of the filters. All filters were labeled and placed in their own labeled plastic bag. Copies of data forms and bagged samples were shipped to the USGS laboratory in Virginia, USA, where they were analyzed using qPCR techniques (Boyle et al. 2004; Kirshtein et al. 2007).

Results.—Quantitative PCR analyses detected the presence of *Bd* in 5 of 9 water samples (Table 1). There were no *Bd* zoospores detected in the control sample. All three stream samples were positive for *Bd* zoospores, and two of the five bromeliad water samples tested positive for *Bd* zoospores (Table 1). The two positive bromeliad water samples were from plants that had the canopy-dwelling tree frog, *Isthmohyla picadoi* (Hylidae), in the plant or nearby (~1 m away).

Discussion.—These findings are significant because they confirm the presence of *Bd* at a site where declines of the local amphibian fauna have occurred (pers. observ.). Mortalities now believed to be caused by *Bd* were first observed in this area (Cerro Pando) in July 1994 (pers. obs.). Mortalities were directly observed in two species, *Atelopus chiriquiensis* and *Rana warszewitschii* (single dead individual of each species). Neither of these species was observed at our study site during three weeks of field research in January 2008. The apparent decade-long persistence of *Bd* has sobering implications for the prospects of repatriating susceptible amphibian species (Fellers et al. 2007).

In addition, while water filtering has been used to detect the presence of *Bd* zoospores in temperate, lentic waters (Kirshtein et al. 2007; Walker et al. 2007), to our knowledge this is the first published report of environmental testing using this technique in neotropical regions and lotic waters. The levels of *Bd* zoospore equivalents in our lotic samples were within the lower range of levels reported from temperate, lentic systems (Kirshtein et al. 2007; Walker et al. 2007; C. Anderson, pers. comm.). Tropical stream-dwelling amphibian species from moderate to high elevations in Central America have experienced inordinate levels of decline (Lips et al. 2003; Pounds et al. 2006), and Kriger and Hero (2007) found a greater prevalence of *Bd* infection among stream breeding amphibians in Australia. Consequently, the ability to detect the presence of *Bd* in lotic waters should prove vital to better understanding *Bd* ecology (Walker et al. 2007). The technique described herein is suitable even when low amphibian abundance prohibits skin swab sampling.

Although there are no known published accounts of *Bd* in arboreal water sources, a study by Longcore (2005) documented the presence of the fungal groups Chytridiomycota, Oomycota, and Hypochytridiomycota from canopy detritus samples obtained in New Zealand and Australia. Twelve of the species detected by Longcore (2005) were chytrids. We report the first published account of *Bd* in arboreal water sources. Our values are ~10x higher than any published samples acquired via these techniques. For example, Kirshtein et al. (2007) reported a range of 19–454 zoospore equivalents/L, and Walker et al. (2007) described ranges from 0.5 to 262 zoospore equivalents/L. Filtering water as soon as possible is advised, since Hyatt et al. (2007) reported declines in zoospore abundance in water samples that are allowed to settle for longer than 8 h. In addition, Hyatt et al. (2007) indicated that zoospores appear to attach to water containers. Consequently, an improved technique may include rinsing sample bags and filtering the rinsate. The presence and abundance of *Bd* in our arboreal samples suggest that arboreal sites may serve as additional environmental reservoirs,

facilitating the persistence of *Bd*.

Various hypotheses have been proposed to explain how *Bd* persists in the environment, including the presence of a saprophytic form (Johnson and Speare 2003; Longcore et al. 1999) although none has been described for *Bd*. Di Rosa et al. (2007) suggested that we still do not understand the entire life cycle of *Bd*, and they described a new growth form that may represent a persistent encysted-form. Non-vertebrate hosts have been proposed and Rowley et al. (2006) initially asserted that freshwater shrimp were *Bd* vectors, although subsequent studies failed to verify this hypothesis (Rowley et al. 2007). Regional persistence may be explained by reservoir species of amphibians that are not lethally infected (Briggs et al. 2005), and such species are known to occur in some areas (Daszak et al. 2004; Garner et al. 2006; Woodhams et al. 2007). While we have not yet identified a specific amphibian host, it is possible that infected individuals of two canopy-dwelling amphibian species occurring at this site are responsible for shedding *Bd* zoospores into bromeliad water. Work is currently under way to analyze skin swabs of *Isthmohyla picadoi* and *Bolitoglossa* sp. from this study site for the presence of *Bd*.

Acknowledgments.—Funding was provided by the Emerging Scholars Network, Christian Scholars Foundation, Messiah College, and Northwest Nazarene University. We thank Cameron Rutt, Nicole Trimmer and Molly Lindquist for help with field collections, Carlos Alfaro for permission to collect water on Los Quetzales Forest Reserve, Chauncey Anderson for consultation and the USGS Backcountry Chytrid-water Field Protocol, and Julie Kirshtein for consultation and laboratory analysis of field samples. Scientific collecting permits were provided by La Autoridad Nacional del Ambiente de Panamá. We complied with all applicable institutional animal care guidelines and obtained appropriate research permits.

The disease caused by the pathogenic fungus *Batrachochytrium dendrobatidis* (*Bd*), chytridiomycosis, is one of several factors driving the global decline of amphibian populations (Blaustein and Kiesecker 2002; Lips et al. 2006; Muths et al. 2003). *Bd* has been found in amphibians at sites across North America including Minnesota, USA (Ouellet et al. 2005; Woodhams et al. 2008). The prevalence of *Bd* in wild anuran populations in Minnesota is unknown, and motivated the work described herein.

We investigated the occurrence of *Bd* at the University of Minnesota's Itasca Biological Station and Laboratories in Itasca State Park, site of the headwaters of the Mississippi River. Our research objectives were to: 1) verify if *Bd* is present in the park; 2) determine which anuran species are affected by the fungus; and 3) test if there are differences in infection rate among species.

Methods.—We collected frogs in Itasca State Park, Clearwater County, Minnesota in June and July 2008. We collected frogs by hand and with nets at night in breeding ponds and during the day near ponds and wetlands. We rinsed nets with 95% ethanol between outings and wore latex gloves in the field and the laboratory to prevent potential transfer of *Bd* among individuals. A subsample of frogs was toe-clipped and released in the field, but most were vouchered. Toe-clips were collected in individual plastic bags and we extracted genomic DNA immediately upon return to the laboratory. We kept frogs individually in plastic bags from time of capture until they were euthanised in the laboratory. Frogs were humanely euthanised with MS-222 (tricaine methanesulfonate) or topical application of benzocaine (Simmons 2002). MS-222 does not appear to inhibit growth or detection of *Bd* (Webb et al. 2005) and was the preferred method of euthanasia. We clipped one toe and a portion of adjacent webbing to obtain tissues. We stored tissues in 95% ethanol at 4°C until processing. All vouchers were deposited in the Bell Museum of Natural History, University of Minnesota (JFBM).

We extracted genomic DNA from tissues using the Qiagen extraction kit (Qiagen, Valencia, CA, USA) following the manufacturer's instructions. We used polymerase chain reaction (PCR) to amplify a 300-bp fragment consisting of part of internal transcribed spacer 1 (ITS1), ribosomal rRNA 5.8S, and part of internal transcribed spacer 2 (ITS2) using *B. dendrobatidis* specific primers (Bd1a and Bd2a; Annis et al. 2004). PCR was performed in 12.5 μl reaction volumes under the following conditions: an initial denaturation of 94°C for 5 min; 30 cycles of denaturation (94°C for 45 sec), annealing (50°C for 45 sec) and extension (72°C for 1 min); followed by a final extension of 72°C for 5 min. All PCR reactions contained a negative control. PCR products were run on a 1% agarose gel, stained with ethidium bromide and visualized under ultraviolet light. Presence of a strong, defined band approximately 300 bp was considered a positive result.

We sequenced two positive samples to ensure that we had amplified *Bd* rather than non-target DNA. We purified PCR products using Exonuclease I and Shrimp Alkaline Phosphatase (Hanke and Wink 1994). Sequencing was performed using Big Dye (Perkin Elmer, Boston, MA, USA) terminator cycle sequencing on an ABI 3730xl at the Advanced Genetic Analysis Center, University of Minnesota. We used BLAST (Altschul et al. 1990) to verify that sequences were *Bd*.

We tested whether infection rates of *Bd* were significantly different among sampled species and among sampled families of frogs using a Chi-square contingency test. All statistical analyses

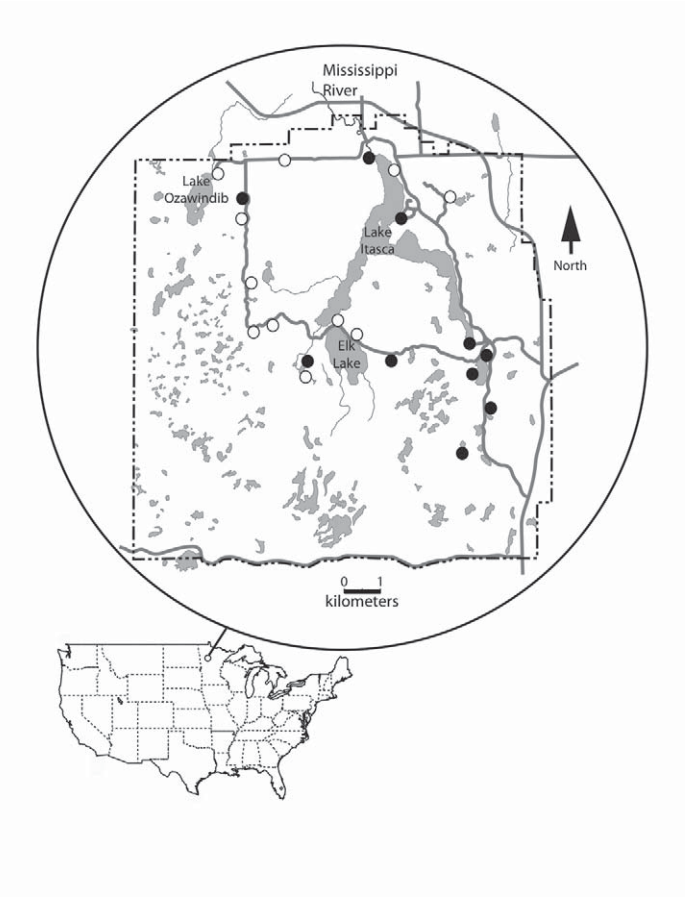

FIG. 1. Collecting locations (circles) of anurans examined for *Batrachochytrium dendrobatitis* (*Bd*) at Itasca State Park, Minnesota, USA. Localities with *Bd*-positive specimens indicated by filled cirlces, localities with no *Bd*-positive specimens indicated by open circles. Park boundaries shown by a dashed line. Light gray areas are water.

were conducted using JMP 7.0 (SAS 2007).

Results.—We collected tissues from 147 frogs and toads of three families from around Itasca State Park (Fig. 1), consisting of 133 vouchered specimens and 14 toe-clips of released frogs. Thirty-four of 147 (23%) individuals were *Bd*-positive. None of our negative controls produced bands on agarose gels. *Pseudacris maculata* had the highest percentage of positive individuals, 50% (Table 1), although it is difficult to interpret this given the small number of individuals captured. *Lithobates pipiens* had the second highest infection rate with 33.3% of samples being *Bd*-positive. *Hyla versicolor* and *Pseudacris crucifer* had no positive samples. We collected one dead *Lithobates sylvaticus* (JFBM 15957) at the Mississippi River headwaters on the North end of Lake Itasca that tested positive for *Bd.* No other dead animals were found, and no animals were observed with symptoms of illness.

TABLE 1. Prevalence of *Batrachochytrium dendrobatidis* in seven frog species collected in Itasca State Park, Minnesota, USA, in 2008.

Species	Family	No. *Bd*-Negative Animals	No. *Bd*-Positive Animals	% Positive (95% C.I.)
Anaxyrus americanus	Bufonidae	20	1	4.8 (0–24.4)
Hyla versicolor	Hylidae	19	0	0 (0–19.8)
Pseudacris crucifer	Hylidae	2	0	0 (0–70.1)
Pseudacris maculata	Hylidae	1	1	50 (9.5–90.6)
Lithobates pipiens	Ranidae	14	7	33.3 (17.1–54.8)
Lithobates septentrionalis	Ranidae	13	3	18.8 (5.8–43.8)
Lithobates sylvaticus	Ranidae	78	22	22 (14.9–31.2)

Rates of *Bd* infection differed among species ($\chi^2 = 16.505$, $P < 0.0113$) and among families ($\chi^2 = 9.673$, $P < 0.0079$). Frogs in the family Ranidae had a higher infection rate than Bufonidae and Hylidae (Table 1).

We confirmed that DNA fragments amplified using PCR were *Bd* by sequencing two of our positive PCR products. Both sequenced samples, one from *Lithobates sylvaticus* (JFBM 15884, Genbank accession number FJ229469) and the other from *Lithobates pipiens* (JFBM 15918, Genbank accession number FJ229470) had an identical sequence. We compared our sequences to *Bd* sequences on Genbank using BLAST, confirming our samples as *Bd.* Our samples had 100% identity with the following *Bd* sequences from Genbank: EU779867, EU779864, EU779863, EU779862, EU779860, EU779859. Our samples had a 98 % identity with *Bd* sequences AY997031 and EU779866.

Discussion.—Rates of *Bd* infection in Itasca State Park varied among species and families. This variance is similar to observations from other North American sites for the same species (Longcore et al. 2007; Ouellet et al. 2005). North American hylid frogs, for example, typically have had low *Bd* infection rates (Longcore et al. 2007; Ouellet et al. 2005; Pearl et al. 2007) and we found no evidence of *Bd* in the hylid species *Hyla versicolor* and *Pseudacris crucifer*. *Pseudacris maculata* and *Acris blanchardi* appear to be exceptions to this rule (Ouellet et al. 2005; Steiner and Lehtinen 2008) and we found one infected *P. maculata* in the Park. We found the highest rates of infection in the three ranid species examined, *L. sylvaticus, L. pipiens* and *L. septentrionalis.* Several hypotheses have been proposed to explain the species-specific variance in *Bd* infection rates. Because *Bd* can persist in aquatic environments (Johnson and Speare 2003), species that spend more time in the water are thought to be at greater risk of infection than species spending less time in the water (Hero et al. 2005; Lips et al. 2003). *Bd* is prevalent in species breeding in permanent wetlands and streams (Kriger and Hero 2007) and in species that overwinter in aquatic environments (Longcore et al. 2007). There is also, potentially, a phylogenetic component to *Bd* (Corey and Waite 2008) with some amphibian lineages showing greater susceptibility to chytridiomycosis than others.

The presence of *Bd* in multiple frog species in Itasca State Park highlights the pathogen's pervasiveness in North America. North American amphibian populations have been exposed to *Bd* since the early 1960s and have been found across the continent (Ouellet et al. 2005). Presence of *Bd* does not always lead to mortality or population declines (Retallick and Miera 2007) but, given its potential as a pathogen, the presence of the fungus is cause for further monitoring of infected populations.

Acknowledgments.—We thank Dede Olson and two anonymous reviewers for helpful comments on the manuscript and Andrew Simons and Ken Kozak for access to lab space. Special thanks to the students of the Global Change and Ecology Program for help in the field. As scientists in the 1990s became aware that amphibian populations were experiencing population declines on a number of continents, the most perplexing mortalities were those observed in relatively pristine environments in which man-made habitat destruction, introduction of invasive species, or direct application of toxicants were not evident. Mass mortalities of amphibians in these relatively untouched environments, such as wilderness areas of the American West and tropical rainforests in Australia and Central America, shared a number of similarities that suggested a common proximate cause. These similarities were: 1) mass mortalities were observed principally in metamorphosed amphibians; 2) populations experienced severe declines in size, and, in some cases, total extinction; 3) only some of the amphibian species in a given locality experienced declines; and 4) population declines were more pronounced at higher elevations or in cooler regions than in lower/warmer areas (Lips 1998; Carey et al. 1999). Many of the mass mortalities sharing this pattern have now been attributed to a chytrid fungal pathogen, *Batrachochytrium dendrobatidis* (hereafter *Bd*; Berger et al. 1998; Skerratt et al. 2007). The observations that *Bd* is more likely associated with mass mortalities of amphibians at higher elevations in mountain ranges than in the adjacent lowlands have been replicated on several continents. For instance, numerous mass mortalities have been noted above approximately 400 m in Costa Rica and Panama (Lips 1998; Lips 1999; Young et al. 2001) but, even though *Bd* has been documented histologically on a number of species living at lower elevations in these countries, no mass mortalities have been observed (Puschendorf et al. 2006). Die-offs are most pronounced at elevations over 400 m in Australia (McDonald and Alford 1999 and above ca. 2000 m in Spain (Bosch et al. 2001; Bosch and Martinez-Solano 2006).

Woodhouse's Toads *(Anaxyrus woodhousii)* (formerly *Bufo woodhousii*; Crother 2008) are widely distributed in the US throughout the western central plains and Rocky Mountain states, from Montana and South Dakota south to Arizona and Louisiana. In Colorado, this species generally occurs at lower elevations up to ca. 2100 m. It is replaced at higher elevations by Western Toads (*Anaxyrus boreas*) (formerly *Bufo boreas*; Crother 2008) which range from about 2500–3550 m (Livo and Yackley 1997). Only one area of sympatric occurrence of the two species has been reported in Colorado (Hammerson 1999; Harris 1963). Western Toads are very susceptible to *Bd* (Carey et al. 2006). Beginning in the 1970s, Western Toad populations have experienced numerous mass mortalities that have extirpated breeding populations from about 85–90% of their historical habitats (Carey 1993; Corn et al. 1989). Some of these mass mortalities have been attributed to *Bd* (Carey et al. 1999; Muths et al. 2003). In a few instances, Woodhouse's Toad carcasses have been observed in the wild, but the deaths could not be attributed to *Bd*. Some carcasses were observed during one study in Arizona, but the carcasses were too decomposed to analyze for the presence or absence of *Bd* (Sredl 2000). Additionally, one of us (LL) found a dead Woodshouse's Toad in Canyonlands National Park, Utah (17 August 1992, ca. latitude 38.06814, longitude 109.76871) and two dead Woodhouse's Toads at Colorado National Monument, Colorado (24 June 1999, latitude 39.01993, longitude 108.64672). Toads at both of these locations were very decomposed and observed before a PCR test for *Bd* was developed. However, to our knowledge, no observations of mass mortalities of Woodhouse's Toads attributed to *Bd* have been recorded in the literature (see Sullivan 2005). Therefore, the goal of this study was to determine whether or not *Bd* is present on Woodhouse's Toads in Colorado.

A total of 86 Woodhouse's Toads were collected at a number of sites, the elevations of which ranged from 1096 to 2032 m (Table 1). Elevation for each sampling site was determined by plot-

ting the GPS coordinate as decimal degrees (WGS84 datum) with National Geographic TOPO! software (Version 3.4.3). When two or more individuals were sampled within a 10 km distance on the same date and the same drainage complex, the individual sites were combined into a single locality for which the mean elevation and latitude/longitude were calculated. We selected a 10 km distance because Woodhouse's Toads in our sampling areas would encounter fewer barriers to movement within a drainage complex than Western Toads in the mountains of Colorado. This latter species has been reported to move straight-line distances of at least 7–8 km between breeding sites (Lambert and Gaughan 2007), which, when following drainages rather than traversing intervening mountains, would result in movement estimates of more than 15 km.

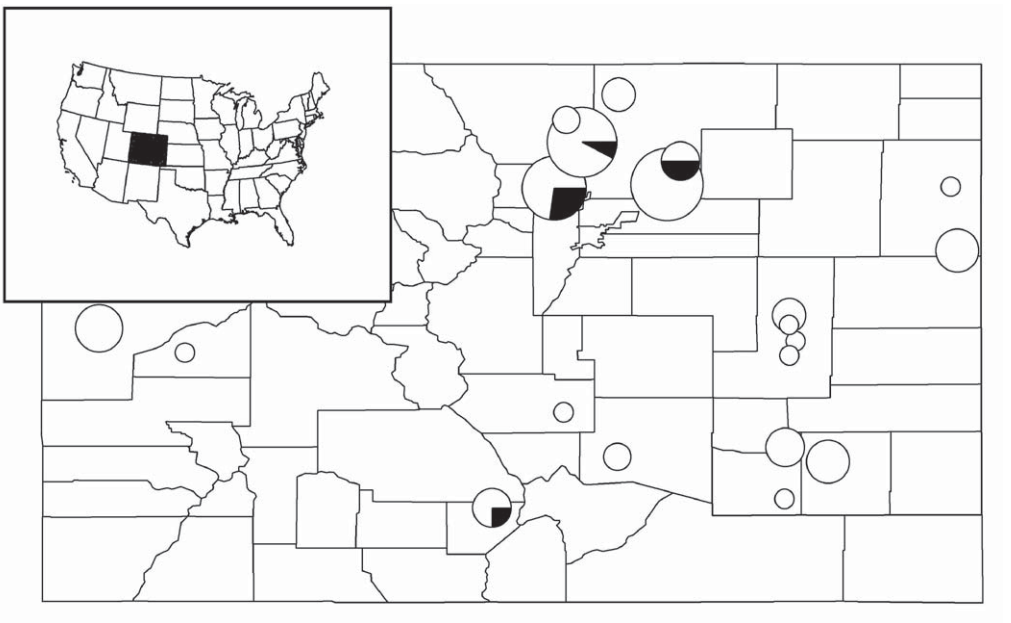

FIG. 1. *Anaxyrus woodhousii* sampling localities (circles) within counties in Colorado, USA. Within circles, open areas represent PCR-negative and black areas represent PCR-positive *Batrachochytrium dendrobatidis* samples. The relative size of each circle is proportional to the total sample size of Woodhouse's Toads. Circles are centered on the localities they represent. In one case, two circles are superimposed: samples were taken at the same location in two separate years.

Each animal was handled with a fresh pair of latex gloves. The ventral pelvic area and back legs were swabbed according to the method of Livo (2004). Swabs were placed in 2-ml vials with 70% ethanol and analyzed for *Bd* DNA by Pisces Molecular LLC, Boulder, Colorado.

Woodhouse's Toads tested positive for *Bd* at several sites in Colorado (Table 1; Figure 1). Unfortunately, we have been unable to revisit the sites with sufficient frequency to determine whether population sizes are declining at the *Bd*-positive sites. At several localities at which one or more Woodhouse's Toads tested posi-

TABLE 1. *Anaxyrus* (*Bufo*) *woodhousii* that tested positive (P) and negative (N) for *Batrachochytrium dendrobatidis* (*Bd)* in Colorado, USA. *Bd*/Other Species indicates whether individuals of other amphibians sampled on the same date at the same locality were all *Bd* negative (N) or any were *Bd* positive (P). tive, other amphibian species also tested positive. In two cases (locations: Hugo, Lincoln County; Vogel Canyon, Otero County), another species tested positive but the Woodhouse's Toad samples were negative. While the presence of *Bd* on a single animal is sufficient to indicate that a locality is *Bd*-positive, small sample sizes at the localities at which all samples tested negative for *Bd* preclude judging whether or not *Bd* is actually present.

Some of the Woodhouse's Toads that were PCR positive for *Bd* were taken to our laboratory at the University of Colorado and subsequently died within 2–3 weeks after capture with many of the signs of chytridiomycosis (i.e., abnormal shedding patterns, lassitude, and decreased blood ionic concentrations; Carey and Livo, unpubl. data), although the presence of and severity of infection have not yet been histologically verified. Additionally, when newly captured Woodhouse's Toads have been experimentally exposed to *Bd* using standardized methods, they all died and were PCR positive for *Bd*. We tentatively conclude that Woodhouse's Toads are at least mildly susceptible to *Bd* infection and that the infection can prove lethal under laboratory conditions. However, whether or not *Bd* causes declines in Woodhouse's Toad populations in the wild deserves more research.

The effect of temperature on *Bd* growth may explain, in part, observations that amphibians living at lower elevations do not experience population declines due to *Bd* (cf. Puschendorf et al. 2006), whereas adjacent high elevation populations do. Exposure of an infected animal to 30°C can control or even kill *Bd* (Woodhams et al. 2003; Carey and Livo, unpubl. data). Amphibians living at higher elevations do not achieve such high temperatures for sufficiently long times to kill *Bd* (Carey 1978; Carey et al. unpubl. data) and, as a result, are unable to shed the fungus once they become infected.

Acknowledgments.—This study was supported by a subcontract to CC from the National Science Foundation grant IBN-9977063 and DEB-0213851 (J. Collins, P.I.) and grants from the Colorado Division of Wildlife to LL.

John Daly—pioneering chemist, pharmacologist, and field herpetologist—died from sepsis associated with pancreatic cancer on March 5, 2008, in Rockville, Maryland. This brief history celebrates a career that fundamentally advanced basic and applied research in biology and medicine. We see frogs and birds and tiny creatures on the jungle floor in new light because of his enthusiastic study of things small and wonderful.

John was born on June 8, 1933 to John E. Daly and Hilda Daly in Portland, Oregon. He received degrees in Biochemistry (B.S., 1954) and Organic Chemistry (M.A., 1955) at Oregon State College, and a Ph.D. (1958) in Organic Chemistry at Stanford University. This was followed by a two-year postdoctoral appointment (1958–1960) at the National Institutes of Health (NIH), in what was then called the National Institute of Arthritis and Metabolic Diseases.

John's appointment was to Bernhard Witkop's Laboratory of Chemistry. Witkop allowed a degree of freedom to his postdoctoral chemists, and John spent time studying catecholamine neurotransmitters under the mentorship of Julius Axelrod, a section chief in a different NIH institute (Mental Health). Axelrod, who received a Nobel Prize for his work on catecholamines in 1970, later remembered (in 1998) that "John somehow drifted to our lab, and I was struck by his intense interest in research."

John was to spend all his professional life at the NIH institute that eventually became (in 1986, after two previous names) the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK). He was appointed to the permanent staff as Research Chemist in Witkop's Laboratory in 1960, became Chief of the Section on Pharmacodynamics in 1969, and became founding Chief of his own Laboratory of Bioorganic Chemistry in 1981.

John became a NIH Scientist Emeritus in January 2003 and enthusiastically continued his research on frog toxins nearly to the week of his death. He is survived by his daughters, Kathryn Daly and Shannon Ostrander, his sister, Hildred Powers, four grandchildren, and his life partner Kathleen McKnight.

During five decades at NIH, John's research spanned several disciplines. The isolation, structural determination, and synthesis of novel natural products was only one interest. He also was especially keen on elucidating the pharmacodynamics of such products, with emphasis on receptors, ion channels, and second messenger formation in the nervous system. Some high points in his career included major discoveries and co-discoveries such as the "NIH Shift"—a surprising molecular mechanism that occurs during conversion of the amino acids phenylalanine and tryptophan to the crucial neurotransmitters dopamine, norepinephrine, and serotonin; the finding that forskolin, from the plant *Coleus*, directly activates adenylyl cyclase, an enzyme responsible for the formation of the intracellular messenger cyclic adenosine monophosphate (cyclic AMP) from ATP; the introduction of a prelabeling technique for investigation of cyclic AMP generation in intact cells; the introduction of a variety of selective agonists and antagonists as probes and radio ligands for adenosine receptors; discovering that the stimulant effects of caffeine in the central nervous system result from blockade of adenosine receptors; the finding that maitotoxin (the most potent marine toxin, produced by a dinoflagellate) stimulates breakdown of metabolically important phosphoinositide; that the anti-diarrhea drug loperamide is a unique modulator of a capacitative calcium influx pathway and that *N*-substituted dihydropyridines are selective blockers of such channels.

John's work on "frog alkaloids" ("dendrobatid alkaloids") led to a series of equally impressive discoveries after he and his associates worked their way through formidable analytical problems. Up to the 1960s, plants generally were considered to be the sole source of alkaloids (bioactive organic nitrogenous ring compounds). Typical plant alkaloids historically were obtained in quantity and structures determined through classic techniques of chemical degradation; alkaloids in frog skin, however, were to be measured in micrograms rather than milligrams. Thin-layer chromatography, electron-impact and chemical-ionization mass spectrometry combined with gas chromatography were used by the 1970s to separate and characterize small samples of "frog alkaloids." And, fortunately, some frogs occurred in exceedingly dense populations that could be harvested without harm to the species, yielding sufficient material for X-ray crystallography of key structures. Before the end of the century, increasingly sophisticated analytical techniques and improved instrumentation were allowing precise determination of many compounds even in a few mg of skin from a single frog.

Hundreds of previously unknown compounds were discovered and assigned to more than 20 structural classes of alkaloids. Many of the new alkaloids have remarkable pharmacological activity, and some of the new classes are characterized by chemical structures unprecedented in nature. Some of these have become widely used as research tools: batrachotoxin as a selective activator of sodium channels; histrionicotoxins as blockers of nicotinic channels; pumiliotoxins as sodium channel agents with biomedical potential as cardiotonic agents; and epibatidine as a nicotinic agonist with potent analgesic activity 200 times stronger than morphine. Many of these alkaloids became targets of synthetic research in laboratories around the world, and synthetic analogues of epibatidine are in clinical trials for treatment of chronic pain from neuropathies, cancer, and arthritis.

Considering his extraordinarily successful career in the laboratory, few of John's numerous collaborators could have been truly cognizant of his proficiency as a tropical field biologist. But, for over four decades, he was *extensively* involved in fieldwork leading to the discovery of over 800 different alkaloids in frog skin.

John himself identified two factors in the genesis of his tropical work. First, his lab chief Bernhard Witkop had studied curare arrow poisons as a student of Nobelist Heinrich Wieland in Germany and was intrigued by reports of a South American "arrow" (dart) poison derived from frogs. Witkop's curiosity led to an important initial

paper with Fritz Märki, a postdoctoral chemist who returned to Switzerland. John was then drawn into the project, eventually becoming lead scientist in the isolation and characterization of the batrachotoxin alkaloids. The second event was a letter from me, as mused by John in various articles and published interviews: e.g., "Our research at the NIH on further alkaloids from frog skins might have ended with batrachotoxin were it not for a news release [that] drew the attention of a herpetologist ..." (Daly 1998a: 165).

This all started in December 1963, when Witkop first sent the young chemist to Colombia to obtain additional skin extracts from a frog used for poisoning blowgun darts. John's involvement came to my attention in the July 16, 1965 issue of *Medical World News*, in a note titled "Deadly Frogs May Yield Therapeutic Agent." At the time, I was on leave from graduate school for a three-year assignment as Visiting Scientist at the old Gorgas Memorial Laboratory in Panama City (funded by an NIH grant with W. E. Duellman and myself as co-investigators). I had recently discovered a remarkable complex of small, brightly colored toxic frogs in the Bocas del Toro region of northwestern Panama, all or most of which seemed to represent a single species, *Dendrobates* (*Oophaga*) *pumilio*. Colors in different micropopulations collectively encompassed the visible spectrum from red to blue, except for one population of achromatic black-and-white frogs.

FIG. 1. John Daly and one of our pack horses in the western Andes, on the 1970 Colombian expedition. This trip of 43 days was intended to close out a five-year survey of dendrobatid skin alkaloids. Instead, it stimulated further work by Daly that continued until his death in 2008.

I mentioned this "exceedingly common" frog in a letter written on September 7, 1965; John responded on September 22 and made his first of many trips to Panama the following January, during a stop-over on his second excursion to Colombia. Our earliest fieldwork together was limited to a few areas accessible by four-wheel drive near Panama City, but we started collaborating immediately on the *pumilio* project. I sent my assistant with John to several of my collecting sites in Bocas del Toro; they obtained some frog-skin samples in methanol and I mailed additional samples a month later.

It was during our early Panama work that John and I initiated what was to become our field "taste test" for presence of pharmacologically active substances in frog skin. I had mentioned (in my 1965 letter) being puzzled as to why small, brightly colored toxic frogs should have no taste when put in one's mouth. We found that some poison frogs first had to be stressed before toxins are released from granular glands; foot-pinching or skin piercing (as by snake teeth) would do the trick. Touching a stressed frog to the tongue (or frog–finger–tongue) provided a fairly accurate field bioassay for presence of alkaloids. Indeed, the human tongue sometimes seemed more sensitive than early analytical techniques then available at NIH. (Presence of "trace-trace" quantities of a powerful toxin in some specimens of Panamanian *Phyllobates lugubris* was suggested by taste when John's earliest lab tests were negative. Years later, it probably was fortunate that we did *not* taste the new, aptly named *Phyllobates terribilis*.)

A bond was established with my wife Joan and me in Panama, where John became a kind of visiting uncle to our young children, Charles and Tracy. When the time came in 1967 for us to drive back to the U.S., John flew down to travel (and collect) with us as far as San José, Costa Rica. Most of the southern part of the Pan American Highway was a rough, unpaved road in those days and we had scarcely entered Costa Rica when a gear broke in our four-wheel drive carryall. We found a mechanic who had an open-air, dirt-floor garage under a thatched roof. John and I spent anxious hours sitting on boxes, apprehensively watching our cheerfully confident mechanic figure out how to get into the transfer case and fabricating his own tool for one process. That done, he took a bus to the nearest Chevrolet dealership back in Panama and the next day smuggled the needed gear under his belt in order to circumvent Costa Rican customs.

While waiting for our mechanic's return, John and nine year-old Charles and I took a ride in a *cazadora* (a "hunter"), the name then applied to tiny country buses. We got off at a good section of forest

to look for poison frogs. We found two species along a stream that also harbored a surprisingly large population of fer-de-lance snakes. But most of our day was spent waiting for *cazadoras*, with no inkling that John and I were to do a lot of waiting together in coming years—waiting sometimes days at a stretch when bad weather kept planes or helicopters from reaching us at a backcountry landing strip or on some mountain top.

We published the results of our early Panama work in *Science* in 1967. The new alkaloids were mistakenly characterized as "steroidal," but never mind, John was to work on that amazing complex of frogs on-and-off for the next 40 years. But it was early days in 1967 and we were wondering about the extent of variation in skin alkaloids of dendrobatid frogs generally. After a field trip to Venezuela, we innocently decided that one trip to Colombia would allow us to wrap up the work started a few years earlier in Panama. The taxonomic diversity of poisonous frogs in Colombia would be sufficient for testing our hypothesis. The brightly colored species would all contain skin toxins that would be found to vary, but all the toxins probably would prove to be steroidal alkaloids—variations on a common theme. How wrong we were about the last part of that! Instead of finalizing the work, we caught the tail of the proverbial tiger and were unable to let go. Well, I might have let go, but John's enthusiasm could not be quelled.

Our first joint trip to Colombia lasted some 40 days in early 1970, during which time John and I covered thousands of kilometers by jeep, on foot, and by dugout canoe. We drove over much of highland and lowland northern and western Colombia and south nearly to Ecuador and into the Amazon basin. We drove to the end of an unpaved road in the western Andes, left our jeep and trekked a day-and-a-half with a few men and pack horses down to the Pacific lowlands, where we traveled by dugout to a collecting site (Fig. 1).

That was to have been our final trip, but back at NIH the field samples yielded dozens of new compounds in new classes of alkaloids. The tiger was running and over the next 30 years John and I worked together in eight tropical countries in the New World, with each of us also making independent trips to several of those countries. An annual field trip was not enough. Two or three trips a year were not uncommon in the 1970s and 80s, and the new alkaloids multiplied into the hundreds. It was an intensive program of discovery, with each new trip yielding treasures of new compounds and often new amphibians and reptiles as well, including a fearsomely toxic frog used by Emberá Chocó Indians as a source of poison for blowgun darts (Figs. 2, 3).

FIG. 2. John Daly at the front steps of a 1973 base camp, an Emberá Chocó house in the Pacific lowlands of western Colombia. This was the general type locality of the dangerously toxic new dart-poison frog that we later named *Phyllobates terribilis*.

FIG. 3. John skinning *Phyllobates terribilis* for methanolic extraction of batrachotoxin alkaloids (1973); in addition to surgical gloves, he is wearing eye and respiratory protection. Batrachotoxin and homobatrachotoxin are among the most potent of all naturally occurring nonprotein toxins. These alkaloids are present in largest quantities (700–1900 μg) in skin of wild-caught *P. terribilis*—the world's most poisonous frog.

During the early work in Colombia we wondered aloud whether the "dendrobatid toxins" were synthesized by the frogs or sequestered from dietary sources. To test the last possibility, we extracted fresh stomach contents of a few common species of dendrobatids into methanol, but John was unable to detect alkaloids or potential precursors in those samples and we came to assume that the frogs themselves were inventive chemists. However, neither was he able to demonstrate biosynthetic pathways in a 1971 experiment with David Johnson; there was no incorporation of radioactive cholesterol, acetate, or mevalonate into the steroidal batrachotoxins of *Phyllobates* or the bicyclic or tricyclic alkaloids of *Dendrobates* (although cholesterol had been recently claimed as a precursor of

certain toad toxins and salamander alkaloids). And F_1 progeny of dart-poison frogs raised at the American Museum lacked detectable alkaloids, although they retained an altered sodium-channel that made them immune to their parents' toxins.

We continued to publish as though the frogs were making their own toxins, as seemed consistent with the absolute novelty of many of the alkaloids and the absence of toxicity in stomach contents. But it was a vexing problem in the back of John's mind, renewed by conversations with colleagues and by growing evidence that ants (a major food source) also were a source of interesting alkaloids. I recall John and the late A. Stanley Rand idly talking in Panama about how one might set about doing a "natural" feeding experiment using captive-raised frogs. That idea eventually bore fruit in 1994, when John and Stan and associates demonstrated uptake of alkaloids by froglets raised in outdoor screened enclosures provided with leaf litter from native habitats; some alkaloids also were obtained from a sampling of leaf-litter insects.

Also in 1994, John and colleagues demonstrated the presence of an efficient uptake system for sequestering dietary alkaloids in some (aposematic) dendrobatid frogs. These events suggested that the granular ("poison") glands may be primarily storage sites in some anurans rather than (or as well as) the chemical factories we had supposed. John doggedly pursued the sequestering evidence in a series of collaborative papers interspersed among publications on chemistry and pharmacology. The 1990s and first years of the 21st century saw a constant flow of discoveries emanating from what had become "the alkaloid program" in John's Laboratory of Bioorganic Chemistry. He depended greatly on chemists H. Martin Garraffo and Thomas F. Spande, the mainstays of the program who became involved in most aspects of John's later research.

Among John's numerous collaborators who figured importantly in the early frog studies, special mention should be made of Edson X. Albuquerque (School of Medicine, University of Maryland), who helped pioneer the pharmacology of anuran alkaloids; Isabella L. Karle (Naval Research Laboratory, Washington, D.C.), responsible for most of the X-ray crystallographic characterization of key structures; and Takashi Tokuyama (Department of Chemistry, Osaka City University), who continued collaborating for many years in the chemical studies. Many other talented chemists and pharmacologists became involved at various times, as shown by a reading of coauthors in the Bibliography.

I gradually withdrew from the dendrobatid work in the 1990s to give time to other long-term projects, but John tried to keep me abreast of the alkaloid program and joined me in several Venezuelan expeditions ending in 2000. Our young colleague Taran Grant expanded the systematic work and revised all dendrobatoid frogs in a masterful Ph.D. dissertation that, with John's assistance, made appropriate use of published and unpublished alkaloid data. (Grant's dissertation was published in 2006, with a number of honorary coauthors.)

My former postdoc Maureen A. Donnelly (Florida International University) and her student Ralph A. Saporito became associated with the alkaloid program at century's end. They collaborated with John's group on an important series of papers in 2002–2007 that determined major arthropod sources of dietary alkaloids in *Dendrobates* (*Oophaga*) *pumilio*—the Central American poison frog that John had started studying in 1963, on his first trip to Panama.

John's wondrously multifaceted and productive program at NIH serendipitously came to include birds as well as frogs and arthropods. Knowing that John thrived on the improbable, I called him in early April 1991, with news just received by phone from Jack Dumbacher (then a graduate student at the University of Chicago), who had evidence of toxicity in a bird. A few days later, Dumbacher wrote, "The same day that we spoke ... John Daly called and agreed to run some initial tests." The resulting collaboration between Dumbacher and Daly and their associates led to the extraordinary discovery of batrachotoxins on the feathers of some New Guinea birds; these highly toxic alkaloids theretofore had been known *only* from the Neotropical dart-poison frogs (*Phyllobates* s.s.). Two high-profile papers in 1992 and 2000 were followed in 2004 by the report that batrachotoxin had been found in *Choresine* beetles (Melyridae). Such beetles, known to be eaten by the birds, were also suggested as the putative source for batrachotoxin in frogs.

In the 1990s, John was on the road to convincing himself that *all* frog alkaloids must be sequestered. He sometimes would call me (always early morning) when there was new evidence of an arthropod origin for one class of alkaloids or another. I would tease that he could not yet rule out lack of biosynthesis for batrachotoxins, histrionicotoxins, or some other major class. But one morning he called with the news of early evidence that an Australian frog was manufacturing one of its own alkaloids. This was supported in print in 2002, with the added evidence that the frogs (*Pseudophryne*) were synthesizing one class of alkaloids (pseudophrynamines) while sequestering another (pumiliotoxins). Furthermore, biosynthesis of pseudophrynamines appeared reduced in the presence of high levels of dietary pumiliotoxins! As revealed by electron microscopy (Neuwirth et al. 1979), the granular secretory glands of amphibians are morphologically (and physiologically) complex structures, and generalized assertions about their evolution and function cannot yet be made with confidence.

Nonetheless, John and various associates collectively have shown that dietary sequestration, especially from mites and ants, is the principal source of what we originally termed the "dendrobatid alkaloids." The demonstration in 2007 that mites are a particularly major source of dietary *and other* alkaloids was a striking finding, particularly since the aposematic dendrobatids are generally regarded as ant-mite specialists (based on terrarium observations, they are physically unable to swallow prey as large as taken by many other frogs their size). However, one cannot yet justify stating categorically that all alkaloids in all genera and species of dendrobatid frogs are of dietary origin. A secondary dietary origin was shown for a few species, in which a precursor dietary alkaloid can be hydroxylated to a more potent compound in the frog.

The ultimate source of the myriad dietary alkaloids remains an open question. Some eventually may prove to be synthesized by the arthropods, but John fretted for years that symbiotic microorganisms may be involved (as in some marine occurrences of tetrodotoxin). The tropical forest floor has never been a simple place, but now I imagine it as a molecular jungle swarming with amazingly diverse alkaloids of astounding bioactivity—or, as envisioned by John in 1977, "a virtually untapped source of new pharmacologically active agents from the world's rain forests."

Fortunately, such complexity was not foreseen when we started our explorations. Given the state of analytical chemistry at the time, the thought of surveying alkaloids in microscopic mites would have been discouraging even to John. The frogs then seemed to be chal-

lenge enough, and in their pursuit we were enticed onto memorable journeys. Much of our travel involved wilderness expeditions by dugout or on foot with a few local packers and guides. John and I worked comfortably together in the forest and early on I quit worrying about him after realizing that he had a built-in compass and untapped stores of resourcefulness and common sense. He did not take his sense of direction for granted, however, and did carry a compass, being always appropriately cautious. After starting off collecting together, we commonly got separated in the forest, only to meet up again when it was time for a trail lunch. Neither of us fully understood how that worked.

Taran Grant coined the dendrobatid genus-group name *Adelphobates*, in honor of two "scientific brothers." However, Joan called us "The Odd Couple" after a popular TV series. But we seldom disagreed, although it happened one time during a trip from one place to another along the Colombian coast. We had hired a dugout with a small outboard motor, but it rode only a few inches above water once loaded. John loved boats and was unhappy when I insisted that for safety we travel up-coast through mangrove channels; John was an enthusiastic boatman and wanted us off coast, with the wind and salt spray in his face. Once the tide went out we were stranded for hours with some very poor folks, who were living off seafood easily gathered at a river mouth. Biting flies were so unimaginably bad that their daylight hours were mostly spent in close proximity to smoke pots. They kindly lent smoke pots for us to huddle over until the tide filled the mangrove channels, giving me time to contemplate my cautious stubbornness.

Over the years we were to spend much time living for a few days or a week or so with impoverished people in rural tropical America. We rented their porches for hanging our hammocks and some families came to expect our return in following years. I remember one isolated house at the edge of a jungle, where several fierce-looking men were sharing a single machete; there were tears of gratitude when John handed each a new machete. John enjoyed people and many came to adore him, except at one Indian settlement where small children ran screaming from us. They had been told that we were witches who would carry them away if they disobeyed their parents.

We conducted our back-country work with circumspection and little fanfare. Nonetheless, our interest in dart-poisons and other toxins did not go unnoticed at home or abroad. For example: John and I each received a few curiously probing calls from inquisitors with unconvincing cover; a pleasant, curious gentleman managed an assignment to the seat between us on a nearly empty flight that had vacant window and aisle seats in abundance (we pretended not to notice that he had been seated prior to boarding); colleagues in one foreign capital were questioned by officials about our poison work. Such interest was different from that of the occasional military patrol that sought out our camps in remote areas. We thought that it related to the global publicity and paranoia following disclosure that our Central Intelligence Agency had had a secret cache of exotic poisons (e.g., the paralytic shellfish poison saxitoxin) and methods of using them (e.g., suicide pills and the poison-dart pistol unwisely displayed to Congress in 1975). Not all bioweapon material had been destroyed as ordered by President Nixon in 1969; the CIA's supply of saxitoxin was transferred to NIH in the 1970s and ended up in John's lab.

John and I had separate but overlapping research objectives, both heavily dependent on fieldwork and general collecting. The discovery of new species of frogs and new alkaloids often coincided. But we collected amphibians and reptiles generally, often with great enthusiasm on his part. I have vivid memories of this world-renown scientist unceremoniously hurling himself at some small lizard or snake that was trying to scurry or slither into the leaf litter. However, he acceded to my early request that he not catch by hand any brightly-ringed snake. On one of our last trips, John called out that he was standing on a thrashing snake that he optimistically suggested was a coral-snake mimic, to which I soon replied, "It's not a mimic, but keep your foot on it until I decide which end is the head"—another rare specimen bagged thanks to John!

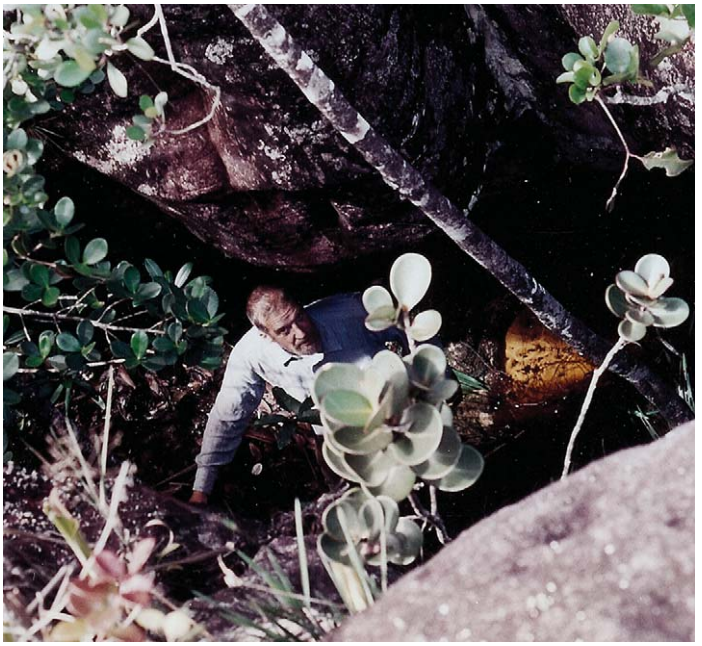

FIG. 4. John in 1994, exploring a sandstone crevasse on the summit of Auyantepui, one of Venezuela's "Lost Worlds."

Fortunately for me and for the American Museum, John was interested from the start in sampling skin secretions of as many kinds of frogs as possible. Many amphibians and reptiles are nocturnal and nighttime collecting therefore is essential. With a powerful light strapped to his head, John joined the ranks of truly accomplished collectors. He was enthralled when the wet tropical forest came alive at night. In the early days I might rush to his side when hearing some exclamation of wonderment, only to find him exchanging stares with some gigantic insect and not the rare frog or snake for which I had hoped. After a day searching for diurnal poison frogs, we often were in the forest until after midnight, resulting in discovery of many previously unknown species of amphibians and reptiles.

John became a global collector, gathering frog-skin samples also in Africa, Thailand, and Australia—sometimes in conjunction with a symposium to which he had been invited. In later years John developed a major field program in Madagascar. But his heart was in the wild places in South America, and from 1989 to 2000 he participated when possible in the American Museum's helicopter-supported expeditions to the Venezuelan *tepuis* (the isolated sandstone mesas such as the one in Sir Arthur Conan Doyle's *The Lost World*). There was little of professional interest to John

FIG. 5. John (left) arriving at camp on a remote Venezuelan table mountain in 2000, for our last fieldwork together.

on these wild, uninhabited mountains, but he loved exploring and was easily persuaded to come lend a hand in the general collecting (Figs. 4, 5). He told me that he came only out of old friendship, but I noticed that his face seemed to light up and his "yes" would come quicker if I slyly mentioned that he might be able to fish in some virgin stream along the way. He usually carried at least a telescoping rod. Fishing in every kind of water was a passion and even the landing of a small piranha seemed fulfilling.

John's research touched many fields and attracted global attention. "During the 1980's [he] was among the 100 most-cited scientists worldwide as documented in *Current Contents*" (fide *NIH Record* August 25, 1998), and for the period 1993–2003, he was 41st among the 100 (of 2,081) most-cited scientists in Pharmacology & Toxicology. Recently, he was said to rank among the 10 most-cited government scientists (*The Pharmacologist* 50:118, June 2008). His work garnered many honors, including: the Hillebrand Award from the American Chemical Society in 1978; the Presidential Rank Meritorious Award, 1989; the Washington Academy of Sciences Award for Outstanding Achievement in the Biological Sciences, 1996; the Japanese Society Fellowship for the Promotion of Science, 1996; the Research Achievement Award from the American Society of Pharmacognosy, 1997; the Karl Wilhelm Scheele Award from the Swedish Academy of Pharmaceutical Sciences, 1999; and the American Chemical Society's Ernest Guenther Award in the Chemistry of Natural Products, 2002. John seemed especially proud of his appointment as Research Associate in Herpetology at the American Museum of Natural History in 1983, and his election to the National Academy of Sciences, USA, in 1997.

John Daly will be missed by the global scientific community. I miss him in ways unforeseen, and he continues to surprise me. Although always generous in his published comments, I was taken aback by his recent, last acknowledgment to me. I did not see it until after his death and for that reason it read like a final farewell. He expressed gratitude for "years of guidance from … his mentor both in the field of herpetology and on their many expeditions to Panama, Colombia, Ecuador, Peru, Venezuela, Suriname, Trinidad, and Brazil." That statement, from an experienced and accomplished field man, says much about John. As one close colleague said, "John was always very kind, even when he should not have been." He was a good friend, a great scientist, and one of the most unpretentious people I have ever known.

Memories and melancholy can be a potent mix. The years of traveling with John have left me with an ever-changing kaleidoscope of remembrances that sometimes come unannounced:

> A certain light at the break of dawn reminds me of John just out of his hammock in back-country Suriname, grumbling at a small scorpion that had taken up overnight residence in the crotch of his trousers.
>
> An exceptionally hard rain might recall the two of us alone in a Colombian cloud forest—in an area where annual rainfall is measured in meters—where we succeeded in having a fire and in keeping our jungle hammocks dry during 13 hours of drenching rain.
>
> A howling gale in the night brings back the montane storm that pushed the side of our tent down across our faces and which would have blown away the tent itself had we not been in it.
>
> Smoke wafting over trees can be reminiscent of the roadless frontier between Venezuela and Brazil, where we helplessly bore witness to a

small missionary plane that crashed and burned in the jungle far below our mountain-top camp.

Sound of a fast boat at night summons our exhilarating, frightening ride in a small speedboat caught after dark between Pebas and Iquitos, racing upriver without life jackets on a flooded Amazon, with logs and uprooted trees coming downstream. One boatman in back running the big outboard motor at full throttle, and one standing in front with a handheld search light spotting the on-coming obstacles and flinging an arm right or left, meaning turn! turn!

Sight of a Boy Scout pocket knife raises the memory of John being arrested during a police raid in a tough Colombian bar. He looked like a sailor and the Scout knife in his pocket a concealed weapon.

I seldom drink beer nowadays. When I do I sometimes remember beers shared with John at the ends of long dusty drives. And perhaps I see the Andean town where we had to hold tight our glasses and raise our legs so that fighting drunks could roll past our table, tumbling out the door and into the horses tied to the rail alongside our jeep.

Treasures of jewel-like frogs at the ends of tropical rainbows. And, along the way, wild towns at the ends of long roads, yes—and wild rivers—and wild places empty of people at the ends of long trails. All that and more did we share, but all trails come to an end. Goodbye old friend, our ways are severed and the jungle has never seemed so dark.

Acknowledgments.—For providing new bibliographic information and for reading and commenting on these "memories," I am deeply grateful to H. Martin Garraffo and Thomas F. Spande, John's long-time colleagues at the National Institutes of Health.

My early travels with John were financed from many sources, including grants from the National Institutes of Health, the National Science Foundation, the Lincoln Ellsworth Fund of the American Museum of Natural History, the Camille and Henry Dreyfus Foundation, the Merck Sharp & Dohme Research Laboratories, Astra Läkemedal AB (Sweden), and the Phipps Foundation. John's participation in my later expeditions (1989–2000) to the Venezuelan tepuis was made possible through the generosity of Robert G. Goelet, former president and Chairman Emeritus of the Board of Trustees of the American Museum of Natural History.

"Herpetological" Bibliography

John's "List of Publications" maintained by his lab contained 655 entries at the time of his death; some additional manuscripts (published, submitted, or in press) bring the minimal total to 666. By my count, at least 213 of these derive from his work on alkaloids and other compounds in the integument of frogs (especially) and other nonmarine animals. Herpetologists and other biologists have started mining data and ideas from some of these publications, but the interdisciplinary tangle and sheer bulk of the work do present a challenge. Many of his publications cannot easily be sorted into categories such as chemistry, pharmacology, biology, or systematics. Some papers span two or more of these disciplines.

This "herpetological" bibliography represents only about 32% of the total of John's published work. It is relevant primarily to amphibians, especially frogs, but some birds and arthropods also are represented, usually because of shared or similar alkaloids.

John's numbering system for the non-steroidal "dendrobatid alkaloids" needs to be understood. When it was realized that such alkaloids were too numerous (now > 800) for each to be given a name such as histrionicotoxin or pumiliotoxin, individual compounds were designated by nominal molecular weight (Myers and Daly 1976a), with identifying letters added to differentiate compounds with identical weights (Myers and Daly 1976b). The system was formalized a few years later (Daly et al. 1978) and the alkaloid designations were then set in boldface for emphasis and to avoid ambiguity when molecular weights are mentioned in discussion. This convention now is widely followed owing to the magnitude of John's work; it has not been used for the small number of steroidal batrachotoxins. For consistency in the bibliography, I have silently bolded molecular-weight/letter designations in a few titles where the practice was not followed.

Pharmacological papers are included in which specific "frog alkaloids" were used along with other molecular probes at one receptor or another. I doubtless have missed some papers in which such alkaloids are not singled out in the title. For practical purposes, such experimental studies may seem irrelevant to whole-animal biology. However, pharmacologic targets of the alkaloids must play a role in the evolutionary dance between prey and predators. John Daly pioneered discovery of an amazing new world of animal alkaloids, whose astonishingly diverse bioactivity is yet to be placed in broad ecological and evolutionary context. It is a new world awaiting further exploration.

NATURAL HISTORY NOTES

The Natural History Notes section is analogous to Geographic Distribution. Preferred notes should 1) focus on observations in the field, with little human intrusion; 2) represent more than the isolated documentation of developmental aberrations; and 3) possess a natural history perspective. Individual notes should, with few exceptions, concern only one species, and authors are requested to choose a keyword or short phrase which best describes the nature of their note (e.g., Reproduction, Morphology, Habitat, etc.). Use of figures to illustrate any data is encouraged, but should replace words rather than embellish them. The section's intent is to convey information rather than demonstrate prose. Articles submitted to this section will be reviewed and edited prior to acceptance.

Electronic submission of manuscripts is requested (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Figures can be submitted electronically as JPG files, although higher resolution TIFF or PDF files will be requested for publication. Please DO NOT send graphic files as imbedded figures within a text file. Additional information concerning preparation and submission of graphics files is available on the SSAR web site at: http://www.ssarherps.org/HRinfo.html. Manuscripts should be sent to the appropriate section editor: **Marc P. Hayes** (crocodilians, lizards, and *Sphenodon*; mhayesrana@aol.com); **Charles W. Painter** (amphibians; charles.painter@state.nm.us); **Andrew T. Holycross** (snakes; AndrewHolycross@gmail.com); and **James Harding** (turtles; hardingj@msu.edu).

Standard format for this section is as follows: SCIENTIFIC NAME, COMMON NAME (for the United States and Canada as it appears in Crother [ed.] 2008. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico*. SSAR Herpetol. Circ. 37:1–84, available from SSAR Publications Secretary, ssar@herplit.com; for Mexico as it appears in Liner and Casas-Andreu 2008, *Standard Spanish, English and Scientific Names of the Amphibians and Reptiles of Mexico.* Herpetol. Circ. 38:1–162), KEYWORD. DATA on the animal. Place of deposition or intended deposition of specimen(s), and catalog number(s). Then skip a line and close with SUBMITTED BY (give name and address in full—spell out state names—no abbreviations). (NCN) should be used for common name where none is recognized. References may be briefly cited in text (refer to this issue for citation format).

Recommended citation for notes appearing in this section is: Medina, P., and R. L. Joglar. 2008. *Eleutherodactylus richmondi*: reproduction. Herpetol. Rev. 39:460.

CAUDATA — SALAMANDERS

***AMBYSTOMA* SP. HABITAT USE.** On 17 May 2007, we observed an ambystomatid salamander inhabiting an unoccupied Gopher Tortoise (*Gopherus polyphemus*) burrow in Baker Co., Georgia, USA. The salamander was observed 3.5 m inside the burrow using a Sandpiper Technologies, Inc. (Manteca, CA) Peeper Video Probe System with a black and white monitor. The nearest potential breeding wetland, a cypress/tupelo swamp, was approximately 1100 m from the burrow. The individual was identified to genus using body size and type, however, species level identification could not be determined. Ambystomatid salamanders occurring in this region include *Ambystoma tigrinum*, *A. talpoideum*, *A. opacum*, and *A. bishopi* (Smith et al. 2006. Southeast. Nat. 5[4]:599–620). At least 60 vertebrate species inhabit gopher tortoise burrows for various reasons (Jackson and Milstrey 1989. Gopher Tort. Reloc. Sym. Proc. 86 pp). To our knowledge, however, ambystomatid salamanders have not previously been reported using Gopher Tortoise burrows. These salamanders spend much of their time underground in burrows they dig themselves or in small mammal burrows (Semlitsch 1983. Can. J. Zool. 61:616–620). We do not know if the salamander inhabited the burrow or was just passing through, although, the presence of leaf litter and the depth of the burrow suggest that the burrow would likely offer suitable shelter for ambystomatids.

Submitted by **AUBREY M. HEUPEL** (e-mail: heup57@gmail.com), **KELLY E. MCKEAN, JENNIFER M. LINEHAN, DAVID A. STEEN,** and **LORA L. SMITH,** Joseph W. Jones Ecological Research Center, Route 2, Box 2324, Newton, Georgia 39870, USA.

DESMOGNATHUS CONANTI (Spotted Dusky Salamander). **HABITAT.** *Desmognathus conanti* is one of the more widely distributed members of the genus, ranging across much of the Southeast and inhabiting a variety of moist environments from stream margins and seepages to muddy swamp edges and mesic forests associated with lowland streams (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington. 576 pp.). To this date, however, many aspects of the ecology and distribution of the salamander remain poorly understood. Here I provide a record for a new type of habitat utilized by *D. conanti* in the Appalachian Plateau region of northern Alabama.

On 15 Sept 2007, individuals of *D. conanti* were encountered on moist talus slopes below several sets of large sandstone bluffs near the Sipsey Fork, near the river's confluence with Borden Creek (34.29222°N, 87.39972°W; WGS84), Winston County, Alabama, USA. The bluffs were ca. 10 m high and ranged in distance from 50–75 m from the stream, situated very high above the water by thick stands of hardwood forest. The talus slopes were extensive beneath each set of bluffs, with available rock cover of varying sizes at each site, and were not directly associated with any type of lotic habitat or pools of standing water. No salamanders were encountered on the forest floor between the bluffs and Sipsey Fork. All individuals were adults and ranged between 47–51 mm SVL.

To my knowledge, this is the first record for this type of habitat use by *D. conanti;* nearly all other recorded habitats involve streamside environments or those directly contiguous to them. However, this species and a congener with similar microhabitat requirements have been found to inhabit crevices in wet cliff environments directly associated with mountain streams (Tilley 1980. Copeia 1980:806–821). It is important to note that individuals of *D. conanti* were also found in several small order tributaries of Sipsey Fork and Borden Creek at sites further upstream from these sandstone bluffs, and with the current drought in the region several other tributaries closer to the bluffs were found to be completely dry with no running water and dry substrate. It has been suggested that extreme drought or flood conditions may cause short-term migrations of *D. conanti* to areas of more suitable habitat. Given that these talus slopes remain shaded all day and were still relatively moist despite extreme drought conditions and dry streambeds nearby suggests that this migratory phenomenon may provide an explanation for our observations. However, a definitive explanation deserves further investigation.

Collected individuals were deposited in the University of Alabama Herpetological Collection (UAHC 15882 and 15883).

Submitted by **WALTER H. SMITH**, Ecology, Evolution, and Systematics Section, Dept of Biological Sciences, Univ. of Alabama, Tuscaloosa, Alabama 35487,USA (e-mail: whsmith1@bama.ua.edu).

GYRINOPHILUS PORPHYRITICUS PORPHYRITICUS (Northern Spring Salamander). **REPRODUCTION**. Few accounts of the nesting activity of *G. p. porphyriticus* exist. Green (1925. Copeia 1925:32) observed a female in attendance of 15 eggs in a spring in Pennsylvania on 8 August. Organ (1961. Herpetologica 17:53–56) observed two nests with females, one with 41 eggs on 14 July and the other with 66 eggs on 6 August in a small spring in southwestern Virginia. Eggs were attached singly in a monolayer to the underside of a rock at least partially submerged in both reports. Bruce (1978. Herpetologica 34:53–64) and Bishop (1924. New York St. Mus. Bull. 253:87–96) both observed similar nests of the Blue Ridge Spring Salamander (*G. p. danielsi*) in North Carolina. Because of the paucity of observed nests, most females probably oviposit in deep underground recesses (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press. 587 pp.); however, nests have not been documented from cave streams. Here, we report a nest of the Northern Spring Salamander from a cave stream located in the Valley and Ridge of east Tennessee.

We observed a female *G. p. porphyriticus* in attendance of a nest on 30 Sept 2007 in Cruze Cave (Tennessee Cave Survey No. TKN24) located in Knox County, Tennessee. The nest consisted of at least 15 eggs attached in a monolayer to the underside of a medium-sized (ca. 30 cm length) rock partially impeded in the cave stream ca. 120 m from the cave entrance. Observable eggs were in a late stage of development. The female was positioned just underneath the nest. We did not have a camera during this trip, and subsequently decided not to disturb the female and nest further. MLN returned a week later on 07 Oct 2007, and only eight eggs near hatching remained and two hatchlings with yolk sacs were observed. The female was no longer in attendance and could not be relocated. The remaining eggs were still attached to the underside of the rock and were submerged in a 4.4 cm deep depression. The hatchlings also were found in the depression and measured 18 and 20 mm TL.

Our observation is consistent with the reports of others that *G. p. porphyriticus* oviposits in summer followed by later summer to autumn hatching (Green 1925, *op. cit.*; Organ 1961, *op. cit.*; Petranka 1998. *op. cit.*). Nests in cave streams have not been reported previously; however, adults and larvae are commonly encountered in cave streams suggesting such habitat is utilized for oviposition.

Submitted by **MATTHEW L. NIEMILLER** (e-mail: mniemill@utk.edu) and **R. GRAHAM REYNOLDS**, Department of Ecology and Evolutionary Biology, University of Tennessee, Knoxville, Tennessee 37996, USA; **JENNIFER G. REYNOLDS**, Oak Ridge Institute for Science and Education, Oak Ridge, Tennessee 37831, USA; and **BRIAN T. MILLER**, Department of Biology, Middle Tennessee State University, Murfreesboro, Tennessee 37132, USA (e-mail: bmiller@mtsu.edu).

RHYACOTRITON OLYMPICUS (Olympic Torrent Salamander). **MAXIMUM LARVAL SIZE**. Data on larval size of torrent salamanders (*Rhyacotriton*) are relatively few. Based on a sample of well over 1000 torrent salamander larvae taken from two sites, one of each of which now falls within the range of *R. variegatus* and *R. cascadae*, Nussbaum and Tait (1977. Amer. Midl. Nat. 98:176–199) reported larval size ranges, respectively, of 13.5–38.6 mm, and 15.8–44.7 mm. Data on variation in larval size are lacking for *R. olympicus*. Here we report an observation of a large *R. olympicus* larva.

On 24 Sept 2007, JAT and KAD made these observations on upper Miller Creek, Mason County, Washington, USA (47.43531°N, -123.15615°W, WGS84; elev. ca. 216 m). Upper Miller Creek is a small (2–4 m wide), third-order perennial stream underlain by Pleistocene glacial till containing interbedded sand, silt, and gravel; however the basalt-based Crescent Formation upstream also contributes large-clast material. Riparian overstory consisted of Red Alder (*Alnus rubra*) and Vine Maple (*Acer circinatum*) with a thin understory of Salmonberry (*Rubus spectabilis*) and Devil's Club (*Oplopanax horridus*); adjacent uplands were second-growth Douglas-fir (*Pseudotsuga menziesii*) managed for timber. At ca. 1000 h, JAT found a *R. olympicus* larva along the shallow (< 2 cm) channel margin. The salamander measured 45.4 mm SVL, 36.8 mm tail length (SVL and tail measured to the anterior end of the vent [*fide* Nussbaum and Tait 1977, *op. cit.*]), and weighed 2.5 g. Though larval, as indicated by its fully developed gills, non-protruding lidless eyes, and tail fins, this animal was probably male as it displayed the distinctive square vent lobes that distinguish post-metamorphic adult males (Good and Wake 1992. Univ. California Publ. Zool. 126:1–91). In the course of sampling for *R. olympicus* in this stream and 12 additional nearby streams over the last three years, this represents the largest *R. olympicus* larva among over 500 animals measured. This animal was also just slightly larger (by 0.7 mm) than the largest *Rhyacotriton* larva previously measured (Nussbaum and Tait 1977, *op. cit*.). After measurement, we released the larva at the location of capture.

We deposited a photographic voucher of this *R. olympicus* at the University of Washington Burke Museum (UWBM 2318). Work was done under a programmatic Washington Department of Fish and Wildlife handling permit provided to employees in the course of their work; conditions of this permit require adherence to the guidelines for use of live amphibians and reptiles in the field (Beaupre et al. 2004. Guidelines for Use of Live Amphibians and Reptiles in Field and Laboratory Research, 2nd ed. Herpetological Animal Care and Use Committee, American Society of Ichthyologists and Herpetologists). This is contribution No. 17 of the Forests and Fish Section of the Washington Department of Fish and Wildlife Habitat Program Science Division.

Submitted by **JULIE A. TYSON, KEITH A. DOUVILLE,** and **MARC P. HAYES**, Washington Dept. of Fish and Wildlife, Habitat Program, 600 Capitol Way North, Olympia, Washington 98501, USA; and **RYAN P. O'DONNELL**, Department of Biology and the Ecology Center, 5305 Old Main Hill, Utah State University, Logan, Utah 84322-5305, USA ([MPH] e-mail: hayesmph@dfw.wa.gov).

ANURA — FROGS

ANAXYRUS AMERICANUS (American Toad). **EGG CANNIBALISM**. Cannibalism by tadpoles on conspecifics may be advantageous when tadpoles occur at high densities in ephemeral breeding sites (Crump 1983. Am. Nat. 121:281–287; Petranka and Kennedy 1999. Oecologica 120:621–631; Dayton and Wapo 2002. J. Herpetol. 36:531–532). Under these conditions, cannibalistic

oophagy may yield especially high payoffs, including not only reduced competition but also an easily accessed source of lipids, proteins, and calcium. Abundant nutrients can promote a decreased time to metamorphosis in an evaporating environment (Heinen and Abdella 2005. Am. Midl. Nat. 153:338–347), thereby increasing odds of survival.

While reports of cannibalistic oophagy are becoming more common for tropical, and especially arboreal anurans, few occurrences have been reported for *Anaxyrus* (reviewed in Petranka and Kennedy 1999. Oecologia 120:621–631; see also Babbitt 1995. Herpetol. Rev. 2:30). To my knowledge, there are no records for cannibalistic oophagy in *Anaxyrus americanus*. Heinen and Abdella (2005. Am. Midl. Nat. 153:338–347) found no evidence for active cannibalism by *A. americanus* tadpoles on conspecifics of same or smaller sizes, but suggested that such cannibalism may be facultative and occur under more stressful environmental conditions (e.g., higher tadpole densities and/or water temperatures) than were encountered by tadpoles in that study.

On 21 May 2006 at Big Creek trailhead (35.4198°N, 82.6755°W; WGS84) in Henderson Co., North Carolina, USA, I observed three pairs of amplexed *Anaxyrus americanus* in a shallow streamside pool at the confluence of Big and Fletcher creeks. Two of the females were laying eggs. All three pairs of adults were surrounded by a very high density of *A. americanus* tadpoles. Tadpoles were congregated on egg strings that were emerging from ovipositing females and many were actively feeding on the eggs (Fig. 1).
